Abstract

Panel data allows for the modeling of unobserved heterogeneity, which significantly increases the number of nuisance parameters, making high dimensionality a practical issue rather than just a theoretical concern. However, unobserved heterogeneity, along with potential temporal and cross-sectional dependence in panel data, further complicates estimation and inference for high-dimensional models. This paper proposes a toolkit for robust estimation and inference in high-dimensional panel models with large cross-sectional and time sample sizes. To reduce the dimensionality, I propose a weighted LASSO using two-way cluster-robust penalty weights. Due to the cluster dependence driven by the underlying components, the rate of convergence is slow even in an oracle case. Nevertheless, by leveraging a clustered-panel cross-fitting approach for bias-correction, the asymptotic normality on low-dimensional parameters can be established using the weighted LASSO for nuisance estimation. In a partial linear model with sparse approximation, I consider a generalized Mundlak device to model the non-additive unobserved heterogeneous effects, and I apply the proposed machine learner, cross-fitting bias-correction, and cluster-robust variance estimator for valid inference. In a panel estimation of the government spending multiplier, I demonstrate how high dimensionality can be hidden and how the proposed toolkit enables flexible modeling and robust inference.

Keywords: high-dimensional regression, two-way cluster dependence, correlated time effects, unobservable heterogeneity, LASSO, Post-LASSO, double/debiased machine learning, cross-fitting.

1. Introduction

In economic research, high dimensionality typically refers to the large number of unknown parameters relative to the sample size, under which traditional estimations are either infeasible or tend to yield estimates too noisy to be informative. The issue of high dimensionality becomes more relevant as data availability grows and economic modeling involves more flexibility. Commonly, the problem of high dimensionality appears in at least the following three scenarios:

- The dimension of observable and potentially relevant variables can be large relative to the sample. In trade literature, preferential trade agreements (PTAs) usually involve a large number of provisions even though most policy analysis only focuses on the effect of a small subset of the provisions ¹. In demand analysis, even if the focus is on the own-price elasticity, the prices of relevant goods should also be included, unless strong assumptions for aggregation are assumed (see Chernozhukov et al., 2019).
- With nonparametric or semiparametric modeling, the unknown functions are viewed as infinite-dimensional parameters regardless of the dimension of observable variables. If the unknown function $g(X)$ is approximately sparse and can be well-approximated by a linear combination of the 3rd-order polynomial transformation of X , then it would involve 285 transformed regressors when the dimension of X is 10 and 1770 when we start with a dimension of 20. ²
- The modeling of heterogeneity can raise the number of nuisance parameters drastically. In demand analysis, income effects are specific to products if the homothetic preference assumption fails. For difference-in-difference analysis, allowing unit-specific trends and heterogeneous trends across the covariates can relax/test the parallel trend assumption. For models with unobserved heterogeneity that appears in a nonlinear way, either treating them as parameters to be estimated (fixed effects) or modeling them in a flexible way (correlated random effects) contributes to high dimensionality. ³.

Particularly, the modeling of heterogeneity in panel models makes high dimensionality more of a practical issue rather than just a theoretical concern. As a concrete example, let's consider a panel model where all three sources of high dimensionality are involved:

$$Y_{it} = D_{it}\theta_0 + g_0(X_{it}, c_i, d_t) + U_{it}, \quad (1.1)$$

where D_{it} is a vector of low-dimensional treatment or policy variables. X_{it} is a vector of potentially high-dimensional control variables. D_{it} can also contain some higher order effects and interactive effects with a subset of the controls to allow for nonlinear and heterogeneous effects in a parametric way. When D_{it} is not conditionally uncounfounded, instrumental variables would be used for identification of θ_0 . ; $g(\cdot)$ is an unknown function, e.g. an infinite dimensional parameter; c_i and d_t are unobserved heterogeneous effects, either as fixed-effect parameters or correlated random variables. The interest lies in the estimation and inference on the low-dimensional parameters of interest θ_0 .

¹Based on data from Mattoo et al. (2020), 282 PTAs were signed and notified to the WTO between 1958 and 2017, encompassing 937 provisions across 17 policy areas. See Breinlich et al. (2022).

²For a vector X with dimension k , it is easy to show that the 2nd-order polynomial transformation generates $\frac{k^2}{2} + \frac{3}{2}k$ terms and the 3rd-order polynomial transformation generates $k + \frac{1}{2}k(k+1) + \frac{1}{2}\sum_{l=1}^k l(l+1) = \frac{1}{6}k^3 + k^2 + \frac{11}{6}k$ terms.

³This is particularly relevant in trade literature where the unobserved heterogeneity derived from the gravity model takes a pairwise form among the importers, exporters, and the time. As each of these three dimensions expands, the number of nuisance parameters explodes quickly. See Correia et al. (2020), Chiang et al. (2021), and Chiang et al. (2023b), for example.

Without considering the features of panel data and the unobserved heterogeneity, it is a classic partial linear model that has been well-studied in previous semiparametric literature. To address the high-dimensional issues in the model, regularization approaches, also known as machine learning, have been employed for estimation, which trades off bias for smaller variance. However, due to the bias introduced by regularization and overfitting, inference is challenging. Typically, some types of bias-correction approaches are involved to obtain desirable statistical properties of high-dimensional estimation and inference approaches.

In a panel data setting, it is soon realized that three challenges would appear if researchers attempt to apply the existing high-dimensional approaches directly. First of all, the statistical properties of many high-dimensional estimators remain unknown with panel data, which is potentially dependent across space and time. Secondly, some bias-correction procedures for inference such as sample-splitting/cross-fitting are very specific to the dependence structure of the data and existing approaches are not valid under two-way dependence in panels. Thirdly, panel data models often consider unobserved individual and time effects, which may lead to another source of high dimensionality and further complicate estimation and inference.

To reduce the dimensionality, as the first challenge, I proposed a variant of LASSO that uses regressor-specific penalty weights robust to two-way cluster dependence and weak temporal dependence across clusters. Such a LASSO approach is named a two-way cluster-LASSO, corresponding to the heteroskedasticity-robust LASSO in Belloni et al. (2012) and the cluster-LASSO in Belloni et al. (2016). This approach identifies the common penalty level λ up to a constant and a small-order sequence that do not vary across different data generating processes. Therefore, data-driven tuning, such as cross-validation, is not needed, which makes it more computationally efficient and to avoid non-trivial theories that take data-driven tuning into account.

A common and important condition for obtaining the desirable statistical properties of LASSO selection/estimation is the so-called "regularization event", which states that the (overall) penalty level is sufficient large to dominate the "noise" in the high-dimensional estimation (but not too large at the same time to avoid under-selection and slow rate of convergence). However, existing approaches for guaranteeing such an event to happen with probability approaching one does not extend to this case due to the two-way cluster dependence. Instead, by considering the component structure characterization of the two-way dependence and decomposing the correlated error terms using Hajek projections, I am able to leveraging the moderate deviation theorems by Peña et al., 2009 and Gao et al., 2022 and the concentration inequality by Fuk and Nagaev (1971) for bounding the tail probability of the "noise" term. Combining with existing non-asymptotic bounds for the LASSO approach in Belloni et al. (2012), I derive the rate of convergence for the (post) two-way cluster LASSO.

According to the rate of convergence results, the proposed (post) LASSO is consistent under certain sparsity conditions. However, it is also revealed that the convergence rate is not as fast as the common rates for LASSO estimation due to the two-way cluster dependence. The problem lies in the underlying component structure. To illustrate, consider the simplest multivariate mean model through a component

structure representation:

$$Y_{it} = \theta_0 + f(\alpha_i, \gamma_t, \epsilon_{it}) \quad (1.2)$$

where Y_{it} is a high-dimensional vector with dimension $s = o(NT)$ and $\theta_0 = E[Y_{it}]$; α_i , γ_t , and ϵ_{it} are unobserved random elements. This is a common characterization of cluster dependence in the literature of cluster-robust inference: we notice that α_i introduce cluster/temporal dependence within group i and γ_t introduce cluster/cross-sectional dependence within group t . To estimate the high-dimensional vector θ_0 , we consider the sample mean estimator $\hat{\theta} = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T Y_{it}$. We can rewrite the estimator through a Hajek projection:

$$\hat{\theta} - \theta_0 = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T (a_i + g_t + e_{it}) = \frac{1}{N} \sum_{i=1}^N a_i + \frac{1}{T} \sum_{t=1}^T g_t + \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T e_{it}, \quad (1.3)$$

where $a_i := E[Y_{it} - \theta_0 | \alpha_i]$, $g_t := E[Y_{it} - \gamma_t]$, and $e_{it} := Y_{it} - \theta_0 - a_i - g_t$. For illustration purpose, suppose those components are i.i.d sequences and independent of each other. Then it can be shown that, under some regularity conditions, for each $j = 1, \dots, s$, $\hat{\theta}_j - \theta_{0j} = O_P\left(\frac{1}{\sqrt{N \wedge T}}\right)$ and $\|\hat{\theta} - \theta_0\|_2 = \left(\sum_{j=1}^s (\hat{\theta}_j - \theta_{0j})^2\right)^{1/2} = O_P\left(\sqrt{\frac{s}{N \wedge T}}\right)$. We see that for $\hat{\theta} - \theta_0$ to have a well-behaved asymptotic distribution (e.g., equipped with finite second moment while not degenerate), we need to scale it by $\frac{1}{\sqrt{N \wedge T}}$ while also requiring both N, T diverging to infinity. This result echoes the rate of convergence the proposed two-way cluster-LASSO, which is $O_P\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right)$ where $\gamma = o(1)$. While $\hat{\theta}$ is still consistent by considering $s = o\left(\frac{N \wedge T}{\log(p/\gamma)}\right)$, $\|\hat{\theta} - \theta_0\|_2$ converges slower than $o_P\left(\sqrt{\frac{1}{N \wedge T}}\right)$. When N, T diverge at the same rate, $o_P\left(\sqrt{\frac{1}{N \wedge T}}\right) = o_P((NT)^{1/4})$, which is a common rate requirement for nuisance estimation to ensure valid inference on the low-dimensional parameters.

This is where the second challenge arises: if a faster rate of convergence is not achievable due to the two-way cluster-dependence, some bias-correction approaches are needed to relax the rate requirement for valid inference. One common approach in semiparametric literature is to add a correction term to the original identifying moment function which can result in an orthogonalized moment condition. As it will be shown later, a sufficient condition for the convergence rate of the first step is $o_P\left(\sqrt{\frac{1}{N \wedge T}}\right)$ using orthogonalized moment condition. This is not a stringent rate requirement in general but it is not achievable under the two-way cluster-dependence as is shown above. An extra bias-correction approach, sample splitting or its generalization cross-fitting, has been proposed for inference in high-dimensional regression models. The idea of sample splitting in a two-step estimation is to split the sample in a proper way and use the sub-samples separately for each step. If the sub-samples are independent of each other, then the first-step estimates will be independent of the sample used for the second-step estimation. With this property, the error term that

causes the bias can vanish with a less stringent rate requirement on the first step. Intuitively, the dependence between the two steps is eliminated so that a potentially over-fitted nuisance estimate from the first step does not pollute the second-step estimator as much as it would otherwise do. However, sample-splitting as well as cross-fitting, as a generalization of sample splitting, is very sensitive to the sampling assumption. Building upon recent development (Chiang et al. (2022); Semenova et al. (2023a)) of cross-fitting approaches for dependent data, I propose a clustered-panel cross-fitting scheme and I show the constructed main and auxiliary samples are “approximately” and independent of each other due to a coupling property attributed to the beta-mixing condition of the unobserved time effects. Effectively, this inferential procedure extends the double/debiased machine learning (DML, hereafter) approach by Chernozhukov et al. (2018a) to panel data models, and so it is labeled as panel DML. Asymptotic normality for the panel DML estimator is established given high-level assumptions on the convergence rates regarding the first-step estimator. It is shown that the crude requirement on the rate of convergence can be relaxed to $o((N \wedge T)^{-1/4})$ in L^2 norm, which admits the first-step estimation through the two-way cluster LASSO.

For the third challenge caused by the unobserved heterogeneity, existing literature has proposed to use fixed-effect or common correlated effect approaches by assuming the unknown function g_0 in 1.1 is linear in (c_i, d_t) (Belloni et al., 2016; Kock and Tang, 2019) or linear in the interactive fixed effects (Vogt et al., 2022). To allow for flexible function forms while remaining tractable, I propose to model (c_i, d_t) as correlated random effects through a generalized Mundlak device while assuming the unknown function to be approximately sparse. In that way, a very rich form of heterogeneity is permitted. While not all of those are relevant and the identity of the truly relevant heterogeneous effects is unknown to the researcher, we can use suitable machine learning approaches, e.g. the two-way cluster-LASSO, to select the relevant effects.

In the empirical application, I re-examine the effects of government spending on the output of an open economy following the framework of Nakamura and Steinsson (2014), a well-cited empirical-macro paper. While they study it using a panel data approach considering unobserved heterogeneous effects that raise the nuisance parameters as the sample size grows, it is not considered as a high-dimensional problem in the baseline setting: a linear panel model with only a few covariates and additive unobserved heterogeneous effects; the identification is through the instrumental variable. However, even in a conventionally low-dimensional setting, high dimensionality can be hidden in the sense that the true model can be highly nonlinear in the covariates and that the unobserved heterogeneous effects can enter the model in a more flexible way. To avoid the endogeneity caused by potential misspecification in the function form, I consider extending the baseline model in a more flexible way as in 1.1, which introduces high-dimensional nuisance parameters. Due to potential two-way cluster dependence, existing high-dimensional methods designed for independent or weakly dependent data may not be valid. This is where the proposed dependence-robust estimation and inference for high-dimensional models can be leveraged and the results can be used for a robustness check. It is shown that the estimates are consistent with the baseline results, which indicates the nonlinear and interactive effects may not be very relevant in this model; other estimation approaches that are not robust to either high-dimensionality or two-way cluster dependence tend to over-fit and result in more noisy estimates

(with larger standard errors).

The rest of the paper is outlined as follows: The next sub-section reviews relevant literature and summarizes the differences and contributions of this paper relative to the existing ones. Section 2 presents the two-way cluster-LASSO estimator and the investigation of its asymptotic properties under two-way cluster dependence. Section 3 introduces a sub-sampling scheme designed for cross-fitting that allows within-cluster dependence and weak dependence across clusters. It is then used as a bias-correction approach for valid inference on the low-dimensional parameter considering the effect of high-dimensional nuisance estimates. In Section 4, the partial linear model with unobserved heterogeneity is studied in detail as a leading example. Simulation evidence is given in Section 5 where the proposed approaches are competed with existing ones. In Section 6, the empirical estimation of the government spending multiplier is used as an illustration of hidden high dimensionality and the application of the proposed toolkit. Section 7 concludes the paper with a discussion of limitations and detailed empirical recommendations.

1.1. Relation to the Literature

This paper builds upon literature on l_1 regularization methods in high-dimensional regression. Bickel et al. (2009) derive the convergence rate of the prediction risk in terms of the empirical norm under homogeneous Gaussian error, restricted eigenvalue, and sparsity assumption. Bühlmann and Van De Geer (2011) instead assumes a sub-Gaussian tail property to derive similar results of convergence rates. See Section 29.11 of Hansen (2022) for an illustration and extension of Bickel et al. (2009)’s analysis under heteroskedasticity. Under Gaussian or sub-Gaussian errors, Basu and Michailidis (2015); Kock and Callot (2015); Lin and Michailidis (2017) study LASSO-based approaches for dependent data. To allow for both non-Gaussian errors and dependent data, Wu and Wu (2016), Chernozhukov et al. (2021a), Babii et al. (2022, 2023) Gao et al. (2024) derive Nagaev-type concentration inequalities to bound the tail probability assuming a proper order of the penalty level. However, all aforementioned LASSO-based approaches require delicate tuning of the penalty level to ensure a desirable finite sample performance. The common cross-validation approaches and bootstrap in Chernozhukov et al. (2021a) for choosing the penalty level are computationally costly and are very sensitive to the sampling assumption. Plus, the statistical analysis accounting for the data-driven penalty level is highly non-trivial (see Chetverikov et al., 2021 for validity on cross-validation LASSO under random sampling). As another strand, Belloni et al. (2011, 2012, 2016) propose other variants of LASSO approaches and leverage (self-normalized) moderate deviation theorems to derive theoretically-driven penalty levels. However, their methodologies cannot be easily extended to the settings with two-way dependence. The proposed variant of LASSO is built upon aforementioned literature and employ both Nagaev-type inequalities (Fuk and Nagaev, 1971) and moderate deviation theorem for self-normalized sums (Peña et al., 2009; Gao et al., 2022). Up to my knowledge, it is the first LASSO and high-dimensional estimator that is robust to the two-way cluster dependence and weak dependence across clusters and the common penalty level is also theoretically driven.

The inferential theory in high-dimensional regression models typically relies on some bias-correction methods and they are particularly important here due to the two-way cluster dependence that results in a slow

rate of convergence. Bias-correction approaches for inference purpose take various forms in the literature: for example, the low-dimensional projection adjustment in Zhang and Zhang (2014), the de-sparsification procedure in Van de Geer et al. (2014), the decorrelating matrix adjustment in Javanmard and Montanari (2014), the double selection approach in Belloni et al. (2014), the decorrelated score construction in Ning and Liu (2017), the Neyman orthogonal moment construction in Chernozhukov et al. (2018a, 2022a). The last strand of the literature is often labeled as the debiased machine learning (DML) approach, which is closely related to previous semiparametric literature including Ichimura (1987), Robinson (1988), Powell et al. (1989), Newey (1994), and Andrews (1994). The idea of the orthogonalization is to add a correction term to the original identifying moment function so that the second-step estimator is less sensitive to the plug-in of noisy first steps. Due to the resulting multiplicative error term in the orthogonal moment condition, it is also related to the doubly-robust literature. Newey (1994) provides a general construction of the orthogonal moment condition through the influence functions. It is further facilitated by Ichimura and Newey (2022) for identifying moment conditions satisfying certain restrictions. See Chernozhukov et al. (2018a) and Chernozhukov et al. (2022a) for a summary of such constructions and known orthogonal moment functions. More recently, Chernozhukov et al. (2018b, 2021b, 2022b,c); Jordan et al. (2023) provide an alternative approach by estimating the correction term without knowing its analytical form. For the inferential theory in high-dimensional panel models, this paper takes the orthogonalization step as given and focuses on nuisance estimation and cross-fitting.

Sample-splitting and cross-fitting serves as another bias-correction approach in this paper has been widely used in many two-step estimations. The role of cross-fitting in high-dimensional inferential theory is to remove the dependence between the nuisance estimation and the second-step estimation so that the over-fitting bias from the first step has less impact on the second step. Technically, it allows for a slower rate of convergence in the first step and it in turn relaxes the sparsity condition (e.g., Belloni et al., 2014). Chernozhukov et al. (2018a) generalize the sample-splitting procedure as a cross-fitting scheme which further improves finite sample performance by reducing the noise due to arbitrary splitting of the sample. Chiang et al. (2021, 2022) propose a cross-fitting scheme robust to separately and jointly exchangeable arrays. Semenova et al. (2023a) propose a leave-one-neighborhood-out cross-fitting and introduce a coupling approach (due to Strassen, 1965 and Berbee, 1987) to prove the validity of cross-fitting under temporal dependence. The idea of leave-one-neighborhood-out sub-sampling scheme is also shared by h -block cross-validation (Burman et al., 1994; Racine, 2000) and big-block-small-block technique in time series literature (e.g., Gao et al., 2022). Built upon previous literature, I propose a more robust cross-fitting scheme that is valid under not only cluster dependence but also weak temporal dependence across clusters.

This paper also belongs to the cluster-robust inference literature. The characterization of the two-way cluster dependence is based on the Aldous-Huber-Kallenberg (AHK) type representation, which is common in this literature (e.g., Djogbenou et al., 2019, Roodman et al., 2019, Davezies et al., 2019, and Menzel, 2021). This original representation only works for exchangeable arrays, which is violated in panel data settings with autocorrelation over time. Chiang et al. (2024) generalizes this representation by allowing the

time factor to be correlated over time and Chen and Vogelsang (2024) also considers this representation when deriving fixed-b asymptotic results for inference. Differing from the original representation theorem, strictly speaking, it is not a representation anymore but more of an assumption and a general characterization of cluster dependence. Such characterization of the dependence structure is common in economics studies (e.g., Rajan and Zingales, 1998, Fama and French, 2000, Li et al., 2004, Larrain, 2006, Thompson, 2011, Nakamura and Steinsson, 2014, Guvenen et al., 2017, Ellison et al., 2024, and Nakamura and Steinsson, 2014 among many others). In this paper, AHK representation introduces dependence both within and across clusters, and the asymptotic variance of the DML estimator has two components: one is due to within-unit dependence and one is due to both within-time dependence and across-time dependence. Therefore, the usual one-way or two-way cluster variance estimator is not valid. I propose variance estimators similar to Chiang et al. (2024) and Chen and Vogelsang (2024), with careful adjustment due to cross-fitting procedures.

1.2. Notation.

Here is a collection of the most frequently used notations in this paper. Some extra notations are defined along with the context. I use E and P as generic expectation and probability operators. I denote \mathcal{P}_{NT} as an expanding collection of all data-generating processes P that satisfy certain conditions. I denote P_{NT} as a sequence of probability laws such that $P_{NT} \in \mathcal{P}_{NT}$. for each (N, T) We will suppress the dependence on (N, T) and P_{NT} whenever clear in its setting. We will use the following vector and matrix norms: we denote $\|\cdot\|$ as the Euclidean (Frobenius) norm for a matrix. Let \mathbf{x} be a generic $k \times 1$ real vector, then the l^q norm is denoted as $\|\mathbf{x}\|_q := \left(\sum_{j=1}^k x_j^q \right)^{1/q}$ for $1 \leq q < \infty$, and $\|\mathbf{x}\|_\infty := \max_{1 \leq j \leq k} |x_j|$. The $L^q(P)$ norm is denoted as $\|f\|_{P,q} := \left(\int \|f(\omega)\|^q dP(\omega) \right)^{1/q}$ where f is a random element with probability law P . I denote the empirical average of f_{it} over $i = 1, \dots, N$ and $t = 1, \dots, T$ as $\mathbb{E}_{NT}[f_{it}] = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T f_{it}$ and the empirical L^2 norm as $\|f_{it}\|_{NT,2} = \left(\frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \|f_{it}\|^2 \right)^{1/2}$. Correspondingly, I denote the empirical average of f_{it} over the sub-sample $i \in I_k$ and $t \in S_l$ as $\mathbb{E}_{kl}[f_{it}] = \frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} f_{it}$, where I_k, S_l are sub-sample index sets and N_k, T_l are sub-sample sizes that will be introduced next section.

2. Two-Way Cluster LASSO

In the literature, not much is known in terms of statistical properties for high-dimensional methods under cluster dependence in both space and time. In this section, a variant of the l_1 -regularization methods, also known as the LASSO, will be constructed and examined. Besides a common penalty level that is theoretically driven, regressor-specific penalty weights robust to two-way cluster dependence and temporal weak dependence across clusters will be utilized. Such a LASSO approach is named two-way cluster LASSO, corresponding to the existing heteroskedasticity-robust LASSO in Belloni et al. (2012) and the cluster-LASSO in Belloni et al. (2016). The intuition is to replace the regressor-specific penalty weights employed in the aforementioned papers with some alternative choices that are robust to two-way cluster dependence in the

panel. However, the valid choices are not immediately clear and the theory is highly non-trivial due to the dependence in both cross-sectional and temporal dimensions.

To focus on the LASSO approach under two-way dependence, I consider a simple conditional expectation model of a scalar outcome given a potentially high-dimensional vector of covariates, and the regression model throughout this section is free from the endogeneity issue caused by unobserved heterogeneous effects. Let (Y_{it}, X_{it}) be a sample with $i = 1, \dots, N$ and $t = 1, \dots, T$. The conditional expectation model can be expressed as follows:

$$Y_{it} = f(X_{it}) + V_{it}, \quad E[V_{it}|X_{it}] = 0 \quad (2.1)$$

where $f(X) := E[Y|X]$ is an unknown conditional expectation function of potentially high-dimensional covariates X and V_{it} is the associated stochastic error.

To characterize the two-way cluster dependence in the panel, I assume the random elements $W_{it} := (Y_{it}, X_{it}, V_{it})$ are generated from the following process:

Assumption AHK (Aldous-Hoover-Kallenberg Component Structure Characterization).

$$W_{it} = \mu + f(\alpha_i, \gamma_t, \varepsilon_{it}), \quad \forall i \geq 1, t \geq 1, \quad (2.2)$$

where $\mu = E_P[W_{it}]$, f is some unknown measurable function; $(\alpha_i)_{i \geq 1}$, $(\gamma_t)_{t \geq 1}$, and $(\varepsilon_{it})_{i \geq 1, t \geq 1}$ are mutually independent sequences, α_i is i.i.d across i , ε_{it} is i.i.d across i and t , and γ_t is strictly stationary.

Assumption AHK is motivated by a representation theorem for an exchangeable array, named after Aldous-Hoover-Kallenberg (AHK, hereafter), which states that if an array of random variables $(X_{ij})_{i \geq 1, j \geq 1}$ is separately or jointly exchangeable⁴, then $X_{ij} = f(v, \xi_i, t_j, \zeta_{ij})$ where $v, (\xi_i)_{i \geq 1}, (t_j)_{j \geq 1}, (\zeta_{ij})_{i \geq 1, j \geq 1}$ are mutually independent, uniformly distributed i.i.d. random variables⁵. However, the exchangeability is not likely to hold for arrays with the presence of a temporal dimension since it is naturally ordered. In macroeconomics, for instance, we can interpret the time components $(\gamma_t)_{t \geq 1}$ as unobserved common time shocks, which are naturally correlated over time, implying the exchangeability violated. Therefore, by allowing γ_t to be correlated, it introduces temporal dependence across all clusters, making the characterization more sensible. The relaxation of the independence condition on $(\gamma_t)_{t \geq 1}$ can be viewed as a generalization of the component structure representation, as argued by Chiang et al. (2024). It is clear that under Assumption AHK, W_{it} and W_{is} are correlated for any i, t, s due to sharing the same cross-sectional cluster. Similarly, due to sharing the same temporal cluster, W_{it} and W_{jt} are dependent for any t, i, j . Furthermore, even if sharing neither the

⁴An array $(X_{ij})_{i \geq 1, j \geq 1}$ is separately exchangeable if $(X_{\pi(i), \pi'(j)}) \stackrel{d}{=} (X_{ij})$, and jointly exchangeable if the same condition holds with $\pi = \pi'$.

⁵This is first proved in Aldous (1981) and independently proved and generalized to higher dimensional arrays in Hoover (1979). It is then further studied in Kallenberg (1989). For a formal statement of the theorem, see, for example, Theorem 7.22 in Kallenberg (2005).

cross-sectional or temporal dimensions, observations can still be correlated due to correlated time effects γ_t . It is important to notice that the components in 2.2 simply characterize the dependence in panel data in a fairly general. Differing from factor models or models with unobserved heterogeneity, they do not affect the identification of the regression model in any way.

Throughout the paper, I consider the time effects γ_t to be weakly dependent, and some regularity condition is introduced for tractability. Before that, a few more concepts and notations need to be introduced. Let (X, Y) be random elements taking values in Euclidean space $S = (S_1 \times S_2)$ with laws P_X and P_Y , respectively. Let $\|\nu\|_{TV}$ denote the total variation norm of a signed measure ν on a measurable space (S, Σ) where Σ is a σ -algebra on S :

$$\|\nu\|_{TV} = \sup_{A \in \Sigma} \nu(A) - \nu(A^c).$$

Define the dependence coefficient of X and Y as:

$$\beta(X, Y) = \frac{1}{2} \|P_{X,Y} - P_X \times P_Y\|_{TV}.$$

The next assumption regulates the dependence of γ_t using the beta-mixing coefficient:

Assumption AR (Absolute Regularity). *The sequence $\{\gamma_t\}_{t \geq 1}$ is beta-mixing at a geometric rate:*

$$\beta_\gamma(m) = \sup_{s \leq T} \beta(\{\gamma_t\}_{t \leq s}, \{\gamma_t\}_{t \geq s+m}) \leq c_\kappa \exp(-\kappa m), \forall m \in \mathbb{Z}^+, \quad (2.3)$$

for some constants $\kappa > 0$ and $c_\kappa \geq 0$.

Condition AR, also known as the beta-mixing condition, restricts the temporal dependence of the common time effects to decay at a certain rate that is common in literature (for example, see Hahn and Kuersteiner (2011); Fernández-Val and Lee (2013), and can be generated by common autoregressive models as in Baraud et al. (2001).

Due to the potential high dimensionality in X , traditional nonparametric methods are not feasible for estimating the unknown function f . To reduce the dimensionality, a common approach is to assume sparsity and reduce the dimension through regularization. However, the unknown function f is an infinite dimensional parameter, which is not exactly sparse. Therefore, I take a sparse approximation approach following Belloni et al. (2012):

Assumption ASM (Approximate Sparse Model). *The unknown function f can be well-approximated by a dictionary of transformations $f_{it} = F(X_{it})$ where f_{it} is a $p \times 1$ vector and F is a measurable map, such that*

$$f(X_{it}) = f_{it}\zeta_0 + r_{it}$$

where the coefficients ζ_0 and the approximation error r_{it} satisfy

$$\|\zeta_0\|_0 \leq s = o(N \wedge T), \quad \|r_{it}\|_{NT,2} = O_P \left(\sqrt{\frac{s}{N \wedge T}} \right).$$

Assumption ASM views the high-dimensional linear regression as an approximation. It requires a subset of the parameters ζ_0 to be zero while controlling the size of the approximation error. Compared to the sparsity assumption in previous literature in high-dimensional regression, it requires a relatively slow rate of growth restriction on the non-zero slope coefficients. For example, $s = o(NT)$ corresponds to the case of heteroskedasticity-robust LASSO under i.i.d data in Belloni et al. (2012); $s = (Nl_T)$ corresponds to the cluster-robust LASSO under temporal dependence panel data in Belloni et al. (2016) where $l_T \in [1, T]$ is an information index that equals T when there is no temporal dependence and equals 1 when there is cross-sectional independence and perfect temporal dependence. In other words, the underlying factor structure restricts the growth of nonzero slope coefficients of the model in a similar way to the perfect temporal dependence case in Belloni et al. (2016).

Under Assumption ASM, we can rewrite the model 2.1 as

$$Y_{it} = f_{it}\zeta_0 + r_{it} + V_{it}, \quad E[V_{it}|X_{it}] = 0. \quad (2.4)$$

Using 2.4, we can estimate ζ_0 allowing its dimension to be greater than the sample size by applying l_1 regularization in the least squared error problem. Let λ be some non-negative common penalty level and ω be some non-negative $p \times p$ diagonal matrix of regressor-specific penalty weights. Consider the following generic weighted LASSO estimator:

$$\hat{\zeta} = \arg \min_{\zeta} \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T (Y_{it} - f_{it}\zeta)^2 + \frac{\lambda}{NT} \|\omega^{1/2}\zeta\|_1. \quad (2.5)$$

To obtain the desirable property of LASSO estimation or variable selection, one needs to choose λ and ω in an optimal way that the penalty level is large enough to avoid noisy estimation due to overfitting but also the smallest possible since the size of penalty determines the performance bound of LASSO estimation and too large a penalty level can cause missing variable bias. In other words, the overall penalty level given by both λ and ω decides the trade-off between overfitting variance and regularization bias. For example, let \dot{f}_{it} be the demeaned f_{it} by the sample averages⁶ and one common choice of ω is the empirical Gram matrix $E[\dot{f}_{it}'\dot{f}_{it}]$ that is used to standardize the regressors and so the model selection is not affected by the scale of the regressors. The common penalty level λ is often chosen by some cross-validation algorithms. If the chosen λ satisfies a certain asymptotic order, then the key condition that regularizes the tail behavior of the

⁶The demeaning is done because of the inclusion of the intercept term. To avoid it to be penalized, it is usually projected out first.

error term can be established under conditional Gaussian error or sub-Gaussian error conditions (see Bickel et al., 2009, Bühlmann and Van De Geer, 2011, and Theorem 29.3 of Hansen, 2022):

$$\max_{j=1,\dots,p} \left| \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \omega_j^{-1/2} f_{it,j} V_{it} \right| \leq \frac{\lambda}{2c_1 NT}. \quad (2.6)$$

Condition 2.6 is referred to as the “regularization event” in the literature. Combining with some algebraic results, the rate of convergence for LASSO estimation can be derived. This approach, however, is not applicable when the error terms are considered to exhibit heavy tails. Alternatively, Fuk-Nagaev types of concentration inequality are established to verify Condition 2.6 without relying on the Gaussian or sub-Gaussian assumption (e.g. Babii et al. (2024, 2023); Gao et al. (2024)). These alternative approaches, again, rely on cross-validation for choosing penalty levels and are computationally costly and sensitive to the tuning of the cross-validation. It is further complicated when the cross-validation needs to be adjusted for dependent data and the validity of cross-validation is highly non-trivial.

Belloni et al. (2012) propose to self-normalize the regressors through regressor-specific penalty weights and leverage moderate deviation theorems (see Jing et al., 2003 and Peña et al., 2009) for the self-normalized sums to verify Condition 2.6. This common penalty level λ though this approach is theoretically derived and only determined by the sample size, the number of regressors, a small-order sequence and some constants that do not vary across data generate processes. When the dependence is considered only in the temporal dimension, then the existing approach for independent data can be extended by clustering over the cross-sectional dimension (see Belloni et al. (2016)). However, there is no simple extension if the dependence is present in both temporal and cross-sectional dimensions. Instead, I utilize the component structure characterization of the dependence and decompose the high-dimensional error term $f'_{it} V_{it}$ using Hajek projection into three components: $a_i = E[f'_{it} V_{it} | \alpha_i]$, $g_t = E[f'_{it} V_{it} | \gamma_t]$, $e_{it} = f'_{it} V_{it} - a_i - g_t$, where a_i are i.i.d over i , g_t are weakly dependent over t , and the remainder can be shown as small order and is well-behaved too. With this observation, I can construct the regressor-specific penalty weights in a way that existing moderate deviation theorems for i.i.d and weakly dependent sums can be leveraged for the first two Hajek components separately while some concentration inequality can be established to the third component.

For that purpose, I propose the following common penalty level λ and (infeasible) penalty weights:

$$\lambda = \frac{C_\lambda NT}{(N \wedge T)^{1/2}} \Phi^{-1} \left(1 - \frac{\gamma}{2p} \right), \quad (2.7)$$

$$\omega_j = \frac{N \wedge T}{N^2} \sum_{i=1}^N a_{i,j}^2 + \frac{N \wedge T}{T^2} \sum_{b=1}^B \left(\sum_{t \in H_b} g_{t,j} \right)^2. \quad (2.8)$$

where $a_{i,j} = E[f_{it,j} V_{it} | \alpha_i]$, $g_{t,j} = E[f_{it,j} V_{it} | \gamma_t]$ for $j = 1, \dots, p$. C_λ is some sufficiently large constant and γ is a small order sequence. The convergence rate of γ affects the convergence rate of the LASSO estimator: as is revealed later, γ should be $o(1)$ for LASSO to be consistent while a larger γ guarantees a faster convergence

rate of LASSO. Again, both C_λ and γ do not vary across different DGPs. While there is some guidance about choosing C_λ and γ through the asymptotic theory, the choice is not given exactly. In practice, it is found that $C_\lambda = 2$ and $\lambda = 0.1/\log(p \vee N \vee T)$ delivers desirable finite sample performance. Looking at the definition of ω in 2.8, we notice that the first term in 2.8 is a variance estimator for i.i.d random variables and the second term is a cluster variance estimator as in Bester et al., 2008 where B is the number of clusters/blocks, h is the block length and H_b is the associated index set. Technically, they are chosen as $B = \text{round}(T/h)$, $h = \text{round}(T^{1/5}) + 1$, and, for $b = 1, \dots, B$, $H_b = \{t : h(b-1) + 1 \leq t \leq hb\}$.

To implement the penalty weights in 2.8, however, we need to estimate $a_{i,j} = E[f_{it,j}V_{it}|\alpha_i]$ and $g_{i,j} = E[f_{it,j}V_{it}|\gamma_i]$ with two challenges. With some initial estimation, we can replace V_{it} with some initial residual \tilde{V}_{it} and then \tilde{V}_{it} can be updated iteratively by the residuals from the estimation in 2.5 until it converges, meaning that \tilde{V}_{it} does not update anymore up to a small difference. A common estimator for $a_{i,j}$ is then $\hat{a}_{i,j} = \frac{1}{N} \sum_{t=1}^T f_{it,j} \tilde{V}_{it}$. Similarly, we use $\hat{g}_{i,j} = \frac{1}{N} \sum_{i=1}^N f_{it,j} \tilde{V}_{it}$ for estimating $g_{i,j}$. Observe that this choice of implementing $\sum_{i=1}^N a_{i,j}^2$ is equivalent to the (unscaled) cluster variance estimator for $\text{Var}(E_{NT}[f_{it,j}V_{it}])$, which is also used as the regressor-specific penalty weights for cluster-LASSO in Belloni et al. (2016). It shows that the first term of ω clusters over time so it adjusts for the temporal dependence within each unit cluster, while the second term clusters over individual first and then clusters over time so it adjusts for cross-sectional dependence within each time cluster and temporal dependence across time clusters. The validity of estimating those components through cross-sectional and temporal averages is given in Menzel (2021) for exchangeable arrays. Extending the consistency results of those sample averages for non-exchangeable arrays is not trivial and establishing the uniform convergence result, required due to the high dimensionality, is rather challenging and not the focus of this paper. Following the practice in Belloni et al. (2012) and Belloni et al. (2016), the asymptotic analysis in this paper is based on high-level assumptions on the feasible penalty weights: Let $\hat{\omega}$ be the feasible diagonal weights and suppose there exists $0 < l \leq 1$ and $1 \leq u < \infty$ such that $l \rightarrow 1$ and

$$l\omega_j^{1/2} \leq \hat{\omega}_j^{1/2} \leq u\omega_j^{1/2}, \text{ uniformly over } j = 1, \dots, p, \quad (2.9)$$

where $\{\omega_j\}$ and $\{\hat{\omega}_j\}$ are diagonal entries of ω and $\hat{\omega}$, respectively.

Observing that the regressor-specific penalty weights can also be interpreted as estimators for $\text{Var}(E_{NT}[f_{it,j}V_{it}])$, the diagonal terms of two-way cluster-robust variance estimators may also be used as the penalty weights. For example, consider the variance estimator proposed in Chiang et al., 2024⁷:

$$\omega_j^{\text{CHS}} = \omega_j^{\text{A}} + \omega_j^{\text{DK}} - \omega_j^{\text{NW}}, \quad (2.10)$$

⁷As it is shown in Chen and Vogelsang (2024), the CHS estimator is algebraically equivalent to an affine combination of a cluster estimator ω_j^{A} (Arellano, 1987), a ‘‘HAC of Averages’’ estimator ω_j^{DK} (Driscoll and Kraay, 1998), and a ‘‘Averages of HACs’’ estimator ω_j^{NW} (Newey, 1994).

where, with $v_{it,j} \equiv f_{it,j} V_{it}$,

$$\begin{aligned}\omega_j^A &= \frac{N \wedge T}{N^2 T^2} \sum_{i=1}^N \sum_{t=1}^T \sum_{s=1}^T v_{it,j} v_{is,j}, \\ \omega_j^{\text{DK}} &= \frac{N \wedge T}{N^2 T^2} \sum_{t=1}^T \sum_{s=1}^T k\left(\frac{|t-s|}{M}\right) \left(\sum_{i=1}^N v_{it,j}\right) \left(\sum_{l=1}^N v_{ls,j}\right), \\ \omega_j^{\text{NW}} &= \frac{N \wedge T}{N^2 T^2} \sum_{i=1}^N \sum_{t=1}^T \sum_{s=1}^T k\left(\frac{|t-s|}{M}\right) v_{it,j} v_{is,j}.\end{aligned}$$

Chen and Vogelsang (2024) propose a two-term version of this estimator by omitting the term ω_j^{NW} due to the observation that the third term is of small order and can introduce finite sample bias. In the extreme case, the three-term estimator ω_j^{CHS} can cause non-trivial encountering of negative variance estimates in the finite sample and it can be alleviated by the two-term estimator

$$\omega_j^{\text{DKA}} := \omega_j^A + \omega_j^{\text{DK}} \quad (2.11)$$

Given consistent residual estimation, Theorem 2 of Chiang et al. (2024) and Proposition 2 of Bester et al. (2008) can be applied to show the point-wise equivalent of the weights in 2.8, 2.10, and 2.11. However, due to the iterative estimation and high dimensionality, showing the uniform asymptotic equivalence of the feasible weights requires extra conditions and is left for future research. All three sets of feasible weights are utilized and compared in the empirical example and the simulation and they do exhibit similar and desirable finite sample behaviors. The implementation of the two-way cluster-LASSO using the feasible penalty weights is given as follows:

Algorithm: Implementation of the Two-Way Cluster-LASSO

- i Obtain the initial residuals \tilde{V} : estimate the model without penalization if feasible; if not feasible, include a certain (user-specified) number of the most correlated regressors.⁸
- ii Set λ according to 2.7 with $C_\lambda = 2$ and $\gamma = 0.1/\log(p \vee N \vee T)$. Calculate $\tilde{\omega}$ according to 2.8, 2.10, or 2.11 using \tilde{V} .
- iii Using $\tilde{\omega}$ for LASSO estimation as in 2.5 and update the residual \tilde{V} using the (post) LASSO estimation.⁹
- iv Repeat steps ii-iii until it converges or up to a pre-set number of iterations. Obtains the (post) LASSO estimates from the last iteration.

Before delivering the main results of the weighted LASSO estimator above, two more sets of regularity conditions are needed. In the low dimensional case, a key identifying condition is that the population Gram

⁸This step is for better convergence of the iterative estimation of the penalty weights. A small number of initially included regressors can cause failure to converge.

⁹While they are asymptotically equivalent, post-LASSO suffers from less shrinkage bias in the finite sample.

matrix $E_P[f_{it}f'_{it}]$ is non-singular so that the empirical Gram matrix is also non-singular with high probability. However, as we allow the dimension of f_{it} to be larger than the sample size, the empirical Gram matrix $E_{NT}f_{it}f'_{it}$ is singular. Fortunately, it turns out that we only need certain sub-matrices to be well-behaved for identification. Define

$$\phi_{\min}(m)(M_f) := \min_{\delta \in \Delta(m)} \delta' M_f \delta \text{ and } \phi_{\max}(Cs)(M_f) := \max_{\delta \in \Delta(m)} \delta' M_f \delta,$$

where $\Delta(m) = \{\delta : \|\delta\|_0 = m, \|\delta\|_2 = 1\}$ and $M_f = E_{NT}[f'_{it}f_{it}]$.

Assumption SE (Sparse Eigenvalues). *For any $C > 0$, there exists constants $0 < \kappa_1 < \kappa_2 < \infty$ such that with probability approaching one, as $(N, T) \rightarrow \infty$ jointly, $\kappa_1 \leq \phi_{\min}(Cs)(M_f) < \phi_{\max}(Cs)(M_f) \leq \kappa_2$.*

The sparse eigenvalue assumption follows from Belloni et al. (2012). It implies a restricted eigenvalue condition, which represents a modulus of continuity between the prediction norm and the norm of δ within a restricted set. More primitive conditions for both types of assumptions are given in Belloni et al. (2012).

Assumption REG (Regularity Conditions). (i) $[E(a_{i,j})^2]^{1/2} / [E(a_{i,j})^3]^{1/3} = O(1)$ for $j = 1, \dots, p$. (ii) $\log(p/\gamma) = o(T^{1/6}/\log T)$ and $p = o(T^{7/6} \log T)$. (iii) For some $s > 1, \delta > 0, \mu > 0$, $E[|f_{it,j}|^{8(s+\delta)}] < \infty$, $E[|V_{it}|^{8(s+\delta)}] < \infty$ and $E[\sum_{t=r}^{r+m} f_{it,j} V_{it}]^2 \geq \mu^2 m$ for all j and $r \geq 0, m \geq 1$. (iv) Either $\lambda_{a,j} := [E(a_{i,j}^2)]^{1/2} > 0$ or $\lambda_{g,j} := [\sum_{\ell=-\infty}^{\infty} E[g_{t,j} g_{t+\ell,j}]]^{1/2} > 0$.

Assumption REG(i) is needed for applying the moderate deviation theorem from Peña et al. (2009). Assumption REG(ii) restricts the dimension of f_{it} while it still allows the size of regressors to be larger than the overall sample size NT . Assumption REG(iii) is used to apply the moderate deviation theorem from Gao et al. (2022) and to show the remainder in the decomposed $f_{it,j} V_{it}$ is of small order. (iv) is again a non-degeneracy condition, which is the main case of interest. The penalty weights given in 2.10, which is used for feasible estimation, are actually robust to both degeneracy and non-degeneracy. However, the theory leverages the moderate deviation theorems based on the self-normalization weights given by 2.8.

A common way to mitigate the shrinkage bias of LASSO is to apply least square estimation based on the selected model by LASSO, which is named Post-LASSO. The next theorem delivers a similar result. Let $\hat{\Gamma} = j \in 1, \dots, p : |\hat{\xi}_j| > 0$ where $\hat{\xi}_j$ are two-way LASSO estimates. In general, $\hat{\Gamma}$ also allows the inclusion of additional variables chosen by the researcher. However, such generalization is not considered in this paper to avoid further complications. As is shown in Belloni et al. (2012), the Post-LASSO is able to achieve rates of convergence no worse than LASSO, and under certain conditions, it improves upon LASSO. This finding is also supported by our simulation. The next theorem gives convergence rates for both two-way cluster-LASSO and its associated Post-LASSO.

Theorem 2.1. *Suppose Assumptions AHK, ASM, AR, SE, REG hold for model 2.1 as $N, T \rightarrow \infty$ jointly with $N/T \rightarrow c$. Additionally, suppose $\hat{\omega}$ satisfies condition 2.9. Let $\hat{\xi}$ be the two-way cluster-LASSO estimator*

or the post-LASSO estimator based on the two-way cluster-LASSO selection. Then, by setting λ as 2.7 with some sufficiently large C_λ , we have the number of selected regressors bounded above by $O(s)$, and

$$\begin{aligned}\frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \left(f_{it} \hat{\xi} - f_{it} \zeta_0 \right)^2 &= O_P \left(\frac{s \log(p/\gamma)}{N \wedge T} \right), \\ \left\| \hat{\xi} - \zeta_0 \right\|_1 &= O_P \left(s \sqrt{\frac{\log(p/\gamma)}{N \wedge T}} \right), \\ \left\| \hat{\xi} - \zeta_0 \right\|_2 &= O_P \left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}} \right).\end{aligned}$$

Theorem 2.1 establishes convergence rates in terms of the prediction, l_1 , and l_2 norms for the two-way cluster-LASSO estimator in an approximately sparse model. These results are the first that give convergence rates for a LASSO-based estimator allowing for two-way cluster dependence. It is shown that under the two-way cluster dependence, driven by an underlying factor structure, the two-way cluster-LASSO is consistent but, unfortunately, has a convergence rate slower than those of LASSO-based methods under the random sampling condition or the cross-section independence. Without loss of generality, let $N = N \wedge T$, then by choosing γ according to $\log(1/\gamma) \simeq \log(p \vee NT)$, we have $\left\| \hat{\xi} - \zeta_0 \right\|_2 = O_P \left(\sqrt{\frac{s \log(p \vee NT)}{N}} \right)$. As a comparison, the rate of convergence in terms of the l_2 norm is $O_P \left(\sqrt{\frac{s \log p}{NT}} \right)$ under the random sampling and the homoskedasticity Gaussian error assumptions in Bickel et al. (2009) or the heteroskedasticity Gaussian error in Theorem 19.3 of Hansen (2022), $O_P \left(\sqrt{\frac{s \log(p \vee NT)}{NT}} \right)$ under random sampling in Belloni et al. (2012), and $O_P \left(\sqrt{\frac{s \log(p \vee NT)}{N l_T}} \right)$ under cross-sectional independence in Belloni et al. (2016) where the information index $l_T = 1$ when there is perfect dependence within the cross-sectional cluster.

As is revealed in the proof of Theorem 2.1 in the Appendix and briefly illustrated in the Introduction, the slow rate of convergence is due to the underlying factor structure. It is unclear if valid inference is still possible under the rate of convergence results in Theorem 2.1. Or, put in another way, what is the minimum requirement of the convergence rates for valid inference in a high-dimensional panel model under two-way dependence? Is it possible to relax the requirement through a cross-fitting procedure? These questions are addressed in the next two sections.

3. Clustered-Panel Cross-Fitting and Inference

In this section, I will first propose a sub-sampling scheme for cross-fitting in a two-way clustered panel and then propose a general inference procedure using cross-fitting for a high-dimensional panel model. The idea of the sub-sampling scheme is to split the sample in a proper way so that two resulting sub-samples are independent or, at least, “approximately” independent. With such properties, the sub-sampling scheme can be used for various purposes. For example, it can be used for cross-fitting in a two-step estimation since it

effectively eliminates the dependence between the two steps, which in turn relaxes the rate of convergence requirement for the first step for valid inference. It can also be used for cross-validation when choosing tuning parameters in panel data models. In this paper, we will focus on its application in cross-fitting. Building upon the cross-fitting algorithm for exchangeable arrays in Chiang et al. (2022) and for weakly dependent panels in Semenova et al. (2023a), I propose a cross-fitting scheme robust to two-way cluster dependence and weak dependence over time.

Let $\{W_{it} : i = 1, \dots, N \text{ and } t = 1, \dots, T\}$ denote a sample of sizes (N, T) from a sequence of random elements $(W_{it})_{i \geq 1, t \geq 1}$ defined on a common measurable space (Ω, \mathcal{F}) and taking values in Euclidean spaces. To allow the dimension of W_{it} to grow with N, T , we denote $(\mathcal{P}_{NT})_{N \geq 1, T \geq 1}$ as an expanding class of probability laws of $\{W_{it} : i = 1, \dots, N \text{ and } t = 1, \dots, T\}$ and denote $P \in \mathcal{P}_{NT}$ as a generic probability law for the sample with sizes (N, T) .

Under the AHK characterization in Assumption AHK, W_{it} are cluster-dependent with both W_{is} and W_{jt} . Importantly, these types of cluster dependence do not vanish as the distance between observations (if there is any ordering) increases. If γ_t is weakly dependent, which is the focus of this paper, then the dependence between observations that don't share the same cluster in either dimension dies out as the temporal distance grows. In that case, intuitively, one can split the sample so that the sub-samples do not share the same cluster and are away from each other in temporal distance. This is exactly how this scheme works:

Definition 3.1 (Two-Way Clustered-Panel Cross-Fitting).

- (i) Select some positive integers (K, L) . Randomly partition the cross-sectional index set $\{1, 2, \dots, N\}$ into K folds $\{I_1, I_2, \dots, I_K\}$ and partition the temporal index set $\{1, 2, \dots, T\}$ into L adjacent folds $\{S_1, S_2, \dots, S_L\}$ so that $\bigcup_{k=1}^K I_k = \{1, \dots, N\}$, $\bigcup_{l=1}^L S_l = \{1, \dots, T\}$ ¹⁰.
- (ii) For each $k = 1, \dots, K$ and $l = 1, \dots, L$, construct the main sample

$$W(k, l) = \{W_{it} : i \in I_k, t \in S_l\},$$

and the auxiliary sample (typically larger)

$$W(-k, -l) = \left\{ W_{it} : i \in \bigcup_{k' \neq k} I_{k'}, t \in \bigcup_{l' \neq l, l \pm 1} S_{l'} \right\},$$

Later on, we also use I_{-k} and S_{-l} to denote the index sets for the auxiliary sample $W(-k, -l)$. Similarly, we denote N_{-k} and T_{-l} as the cross-sectional and temporal sample sizes for the auxiliary sample $W(-k, -l)$. Figure 1 illustrates the cross-fitting with $K = 4$ and $L = 8$.

¹⁰For simplicity, I assume N and T are divisible by K and L , respectively. In practice, if N is not divisible by K , the size for each cross-sectional block can be chosen differently with some length equal to $\text{floor}(N/K)$ and others equal to $\text{ceil}(N/K)$. and the same applies to the temporal dimension.

Figure 1: Clustered-Panel cross-fitting with $K = 4$ and $L = 8$. Three graphs from left to right correspond to the main and auxiliary sample constructions with $(k, l) = (1, 1)$, $(k, l) = (2, 2)$, $(k, l) = (3, 3)$. For a simple illustration, observations in the main sample are all adjacent in the cross-sectional dimension but it is not necessary in practice; the same applies to the auxiliary sample.

Since the sub-samples $W(k, l)$ and $W(-k, -l)$ do not share any cluster, they are free from cluster dependence and what's left is the weak dependence over time. Unless imposing m -dependence, the sub-samples above will not be independent. However, under certain regularity conditions regarding the weak dependence, it can be shown through the coupling technique that as long as the temporal distance between the sub-samples diverges at a certain rate, there exists coupling sub-samples that are independent of each other while having the same marginal distributions as the our constructed sub-samples with probability converging to 1. Such coupling technique is common in time series context and the idea in cross-fitting in time dimension follows from Semenova et al. (2023a). The following lemma delivers such a result

Lemma 3.1 (Independent Coupling). *Consider the sub-samples $W(k, l)$ and $W(-k, -l)$ for $k = 1, \dots, K$ and $l = 1, \dots, L$. Suppose Assumptions AHK, AR hold and $\log(N)/T = o(1)$ as $T \rightarrow \infty$. Then, we can construct $\tilde{W}(k, l)$ and $\tilde{W}(-k, -l)$ such that: (i) they are independent of each other; (ii) have the same marginal distribution as $W(k, l)$ and $W(-k, -l)$, respectively; (iii)*

$$P \left\{ (W(k, l), W(-k, -l)) \neq (\tilde{W}(k, l), \tilde{W}(-k, -l)) , \text{ for some } (k, l) \right\} = o(1).$$

Lemma 3.1 shows that the main and auxiliary samples from the proposed clustered-panel cross-fitting scheme are approximately independent as N, T diverge. Note that the hypothetical sample $\tilde{W}(k, l)$ and $\tilde{W}(-k, -l)$ do not matter in practice, but they allow us to treat $W(k, l)$ and $W(-k, -l)$ as $\tilde{W}(k, l)$ and $\tilde{W}(-k, -l)$ with probability approaching 1. The proof of Lemma 3.1 is based on independence coupling results (Strassen, 1965, Dudley and Philipp, 1983, and Berbee, 1987) introduced in Semenova et al. (2023a).

As mentioned at the beginning of the section, one of the primary uses of the sub-sampling scheme is cross-fitting in a two-step estimation. To be concrete, I will define a two-step estimator using the cross-fitting algorithm in the context of a semi-parametric moment restriction model. The theoretical properties

of the estimator will be studied in Section 3.1.

Let $\varphi(W_{it}; \theta, \eta)$ denote some identifying moment functions where θ is a low-dimensional vector of parameters of interest and η are nuisance functions. For example, $\eta = g_0$ in 1.1. Let $\psi(W_{it}; \theta, \eta)$ denote some orthogonalized moment function based on $\varphi(W_{it}; \theta, \eta)$. The formal definition of the orthogonality will be delivered in the next subsection. For now, it suffices to be aware that both functions are mean zero but $\psi(W_{it}; \theta, \eta)$ is adjusted for the fact that η_0 needs to be estimated. In model 1.1, $\varphi(W_{it}; \theta, \eta) = D_{it}U_{it}$ and $\psi(W_{it}; \theta, \eta) = (D_{it} - E[D_{it}|X_{it}, c_i, d_t]) (Y_{it} - D_{it}\theta - g(X_{it}, c_i, d_t))$. In the treatment effect model with unconfoundedness conditional on covariates and unobserved heterogeneous effects, $\varphi(W_{it}; \theta, \eta) = E[Y_{it}|D_{it} = 1, X_{it}, c_i, d_t] - E[Y_{it}|D_{it} = 0, X_{it}, c_i, d_t] - \theta^{\text{ATE}}$ and $\psi(W_{it}; \theta, \eta)$ is the moment function corresponding to the well-known augmented inverse probability weighting estimator, which is doubly robust.

The panel cross-fitting procedure goes as follows. For each k and l , we use the sub-sample $W(-k, -l)$ to estimate η with the estimator denoted as $\hat{\eta}_{kl}$. For each $i \in I_k$ and $t \in S_l$, we plug-in $\hat{\eta}_{kl}$ to the orthogonal moment function, $\psi(W_{it}; \theta, \hat{\eta}_{kl})$. By averaging $\psi(W_{it}; \theta, \hat{\eta}_{kl})$ across all $k = 1, \dots, K$ and $l = 1, \dots, L$, we obtain

$$\bar{\psi}_{kl} := \mathbb{E}_{kl} [\psi(W_{it}; \theta, \hat{\eta}_{kl})],$$

which is a sample analogue of the population orthogonal moment condition used for estimation. Note that the larger sub-sample $W(-k, -l)$, instead of the smaller sub-sample $W(k, l)$, is used for first-step nuisance estimation because it usually involves high-dimensional unknown parameters. For reference, $W(k, l)$ is referred to as the main sample and $W(-k, -l)$ is referred to as the auxiliary sample. The next definition summarizes the panel DML estimation and inference procedures for a semiparametric moment restriction model:

Definition 3.2 (Panel DML Algorithm).

- (i) Given the identifying moment functions $\varphi(W; \theta, \eta)$ such that $E_P[\varphi(W; \theta_0, \eta_0)] = 0$, find the orthogonalized moment function $\psi(W, \theta, \eta)$.
- (ii) Select (K, L) and then randomly partition $\{1, 2, \dots, N\}$ into K folds $\{I_1, I_2, \dots, I_K\}$ and partition $\{1, 2, \dots, T\}$ into L adjacent folds $\{S_1, S_2, \dots, S_L\}$. For each $k = 1, \dots, K$ and $l = 1, \dots, L$, construct the main sample

$$W(k, l) = \{W_{it} : i \in I_k, t \in S_l\},$$

and the auxiliary sample

$$W(-k, -l) = \left\{ W_{it} : i \in \bigcup_{k' \neq k} I_{k'}, t \in \bigcup_{l' \neq l, l \pm 1} S_{l'} \right\}.$$

- (iii) For each k and l , use the sample $W(-k, -l)$ for the first-step estimation and obtain $\hat{\eta}_{kl}$, then construct

$\bar{\psi}_{kl}(\theta) = \mathbb{E}_{kl}[\psi(W_{it}; \theta, \hat{\eta}_{kl})]$ for each (k, l) . Finally, obtain the DML estimator $\hat{\theta}$ as the solution to

$$\frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \bar{\psi}_{kl}(\theta) = 0. \quad (3.1)$$

Remark 3.1 (The Choice of K and L). Notice there is a trade-off in setting (K, L) between the first step and second step accuracy: the bigger values of (K, L) , the bigger sample size of the auxiliary sample $W(-k, -l)$, which is beneficial for high-dimensional first-steps but at the cost of a noisier parametric second step. In our case, it necessitates an $L \geq 4$ for feasible implementation (if $L = 3$, for example, any main sample $W(k, l)$ with $l = 2$ does not have a well-defined auxiliary sample). On the other hand, it is computationally costly to set the values of (K, L) too large. In practice, $K = 2$ to 4 and $L = 4$ to 8 work well in simulations.

3.1. Panel DML: Inferential Theory

To investigate the required convergence rate of a high-dimensional estimator for valid inference, I will study a general inference procedure for a high-dimensional panel model characterized by a semiparametric moment restriction. Such an inference procedure is based on the panel cross-fitting approach proposed in Section 3 and the prototypical DML approach proposed in Chernozhukov et al. (2018a).

With the same notation from Section 3, the model is characterized by a semiparametric moment condition $\mathbb{E}[\varphi(W_{it}; \theta_0, \eta_0)] = 0$ where W_{it} are again characterized by an underlying component structure as in Assumption AHK. Let $\psi(W; \theta, \eta)$ be the orthogonalized moment function. Formally, the orthogonality means that it is mean zero and its pathwise or Gateaux derivative with respect to the nuisance parameter is 0 when evaluated at the true values:

$$\mathbb{E}_P[\psi(W_{it}; \theta_0, \eta_0)] = 0, \quad (3.2)$$

$$\partial_r \mathbb{E}_P [\psi(W_{it}; \theta_0, \eta_0 + r(\eta - \eta_0))] |_{r=0} = 0. \quad (3.3)$$

In other words, the nuisance functions have no first-order effect locally on the orthogonalized moment conditions, based on which the estimation of θ_0 is therefore robust to the plug-in of noisy estimates of γ_0 . In contrast, the original identifying moment conditions do not possess such a property.

Again, the orthogonal moment construction is taken as given. The panel DML procedure is defined in Definition 3.2. Differing from the existing literature, the approach in this paper focuses on estimation and inference robust to two-way cluster dependence and weak dependence across clusters, characterized by Assumption AHK. Note that Assumption AHK also includes i.i.d data as a special case. Although the panel DML procedure is also robust to the i.i.d case or, more generally, the case of the degeneracy in components, the theoretical properties are not formally given in this paper. The rates of convergence for both the nuisance estimator and the second-step estimator are different and faster for the i.i.d case but that's not surprising and is not the focus of this paper. To restrict the focus, I will assume a non-degeneracy condition in terms of Hajek projection components. First, I define the Hajek components and their corresponding (long-run)

variance-covariance matrices as follows:

$$\begin{aligned} a_i &:= E_P [\psi(W_{it}; \theta_0, \eta_0) | \alpha_i], \quad \Lambda_a \Lambda_a' := E_P[a_i a_i'], \\ g_t &:= E_P [\psi(W_{it}; \theta_0, \eta_0) | \gamma_t], \quad \Lambda_g \Lambda_g' := \sum_{l=-\infty}^{\infty} E_P[g_t g_{t+l}'], \\ e_{it} &:= \psi(W_{it}; \theta_0, \eta_0) - a_i - g_t, \quad \Lambda_e \Lambda_e' := \sum_{l=-\infty}^{\infty} E_P[e_{it} e_{i,t+l}']. \end{aligned}$$

Let $\lambda_{\min}[\cdot]$ denote the smallest eigenvalue of a square matrix. The next assumption specifies the non-degenerate condition.

Assumption ND (Non-Degeneracy). *Either $\lambda_{\min}[\Lambda_a \Lambda_a'] > 0$ or $\lambda_{\min}[\Lambda_g \Lambda_g'] > 0$.*

Assumption ND implies that at least one of the components drives the cluster dependence.

The next two assumptions follow the same format as Chernozhukov et al. (2018a) but, importantly, they characterize some different rates of convergence required for inferential theory. Let a_0 and a_1 be some positive and finite constants such that $a_0 < a_1$. Let (δ_{NT}) and (Δ_{NT}) be some sequence of positive constants converging to 0 as $N, T \rightarrow \infty$. Let \mathcal{T}_{NT} be a nuisance realization set such that it contains η_0 and that $\hat{\eta}_{kl}$ belongs to \mathcal{T}_{NT} with probability $1 - \Delta_{NT}$ for each (k, l) .

Assumption DML1 (Linear Moment Conditions, Smoothness, and Identification).

(i) $\psi(W; \theta, \eta)$ is linear in θ :

$$\psi(w; \theta, \eta) = \psi^a(W, \eta)\theta + \psi^b(W, \eta), \quad \forall w \in \mathcal{W}, \theta \in \Theta, \eta \in \mathcal{T}.$$

(ii) $\psi(W; \theta, \eta)$ satisfy the Neyman orthogonality conditions 3.2 and 3.3 with respect to the probability measure P , or, more generally, 3.3 can be replaced by a λ_{NT} near-orthogonality condition

$$\lambda_{NT} := \sup_{\eta \in \mathcal{T}_{NT}} \|\partial_r E_P[\psi(W; \theta_0, \eta_0 + r(\eta - \eta_0))] |_{r=0}\| \leq \delta_{NT} / \sqrt{N}.$$

(iii) The map $\eta \rightarrow E_P[\psi(W_{it}; \theta, \eta)]$ is twice continuously Gateaux-differentiable on \mathcal{T} .

(iv) The singular values of the matrix $A_0 := E_P[\psi^a(W_{it}; \eta_0)]$ are bounded between a_0 and a_1 .

Assumption DML1(i) restricts the focus of this paper to models with linear orthogonal moment conditions, which covers many applications and the model in Section 4. For nonlinear orthogonal moment conditions, Chernozhukov et al. (2018a) has shown that the DML estimator has the same desirable properties under more complicated regularity conditions. Focusing on the linear cases allows us to pay more attention to issues specifically attributed to panel data. Assumption DML1(ii) slightly relaxes the orthogonality condition 3.3 by a near-orthogonality condition, which is useful for the approximate sparse model considered in Section 4 because the corresponding orthogonal moment condition does not satisfy 3.3 exactly due

to approximation errors. Assumption DML1(iii) imposes a mild smoothness assumption on the orthogonal moment condition and Assumption DML1(iv) is a common condition for identification.

Assumption DML2 (Moment Regularity and First-Steps).

(i) For all $i \geq 1$, $t \geq 1$, and some $q > 2$, the following moment conditions hold:

$$m_{NT} := \sup_{\eta \in \mathcal{T}_{NT}} (\mathbb{E}_P \|\psi(W_{it}; \theta_0, \eta)\|^q)^{1/q} \leq a_1,$$

$$m'_{NT} := \sup_{\eta \in \mathcal{T}_{NT}} (\mathbb{E}_P \|\psi^a(W_{it}; \eta)\|^q)^{1/q} \leq a_1.$$

(ii) The following conditions on the statistical rates r_{NT} , r'_{NT} , λ'_{NT} hold for all $i \geq 1$, $t \geq 1$:

$$r_{NT} := \sup_{\eta \in \mathcal{T}_{NT}} \|\mathbb{E}_P[\psi^a(W_{it}; \eta) - \psi^a(W_{it}; \eta_0)]\| \leq \delta_{NT},$$

$$r'_{NT} := \sup_{\eta \in \mathcal{T}_{NT}} \left(\mathbb{E}_P \|\psi(W_{it}; \theta_0, \eta) - \psi(W_{it}; \theta_0, \eta_0)\|^2 \right)^{1/2} \leq \delta_{NT},$$

$$\lambda'_{NT} := \sup_{r \in (0,1), \eta \in \mathcal{T}_{NT}} \left\| \partial_r^2 \mathbb{E}_P[\psi(W_{it}; \theta_0, \eta_0 + r(\eta - \eta_0))] \right\| \leq \delta_{NT} / \sqrt{N}.$$

Assumption DML2 regulates the quality of the first-step nuisance estimators. It follows from Chernozhukov et al. (2018a) and it can be verified under primitive conditions in the next section. Observe that, if the orthogonal moment function $\psi(W; \theta, \eta)$ is smooth in η , then λ'_{NT} is the dominant rate and it imposes a crude rate requirement of order $\varepsilon_{NT} = o(N^{-1/4})$ on the first-step nuisance parameter in $L^2(P)$ norm, which is possible for the two-way cluster LASSO estimator to achieve under proper sparsity assumption. Furthermore, in some models including the partial linear model, λ'_{NT} can be exactly 0, then it is possible to obtain the weakest possible rate requirement for the first-step estimator, i.e. $\varepsilon_{NT} = o(1)$.

Theorem 3.1 (Asymptotic Normality and Variance). *Suppose Assumptions AHK, AR, ND, DML1, DML2 hold for any $P \in \mathcal{P}_{NT}$, then for some $\delta_{NT} \geq N^{-1/2}$, as $(N, T) \rightarrow \infty$ jointly,*

$$\sqrt{N} (\hat{\theta} - \theta_0) = -\sqrt{N} A_0^{-1} \sum_{i=1}^N \sum_{t=1}^T \psi(W_{it}; \theta_0, \eta_0) + o_P(1) \Rightarrow N(0, V),$$

where

$$V := A_0^{-1} \Omega A_0^{-1'},$$

$$\Omega := \Lambda_a \Lambda_a' + c \Lambda_g \Lambda_g'.$$

We observe that the convergence rate of the two-step estimator $\hat{\theta}$ resulting from the panel DML procedure is non-standard. It is \sqrt{N} -consistent instead of \sqrt{NT} -consistent. This is because the cluster dependence

introduced by the unit and time components does not decay over time or space. Intuitively, with more persistence, the information carried by data is accumulated more slowly. It is a common feature in the literature of robust inference with cluster dependence¹¹ and it is also related to inferential theory under strong cross-sectional dependence as in Gonçalves (2011).

Due to the presence of unit and time components, the asymptotic variance is made of (long-run) variance-covariance matrices of both factors. I consider a two-way cluster robust variance estimator similar to Chiang et al. (2024) (CHS estimator) with adjustment due to cross-fitting. The variance estimator is motivated under arbitrary dependence in panel data and is shown to be robust to two-way clustering with correlated time effects in linear panel models. As is shown in Chen and Vogelsang (2024), such variance estimator can be written as an affine combination of three well-known robust variance estimators: Liang-Zeger-Arellano estimator, Driscoll-Kraay estimator, and the "average of HACs" estimator. Applying this result, we can define the CHS-type variance estimator as follows:

$$\begin{aligned}\hat{V}_{\text{CHS}} &= \hat{A}^{-1} \hat{\Omega}_{\text{CHS}} \hat{A}^{-1'}, \\ \hat{\Omega}_{\text{CHS}} &= \hat{\Omega}_A + \hat{\Omega}_{\text{DK}} - \hat{\Omega}_{\text{NW}},\end{aligned}$$

where, with $k\left(\frac{m}{M}\right) := 1 - \frac{m}{M}$ for $m = 0, 1, \dots, M-1$ and 0 otherwise (i.e., Bartlett kernel) and the bandwidth parameter M chosen from 1 to T_l ,

$$\begin{aligned}\hat{A} &:= \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \frac{1}{N_k T_l} \sum_{i \in I_k, s \in S_l} \psi^a(W_{it}; \hat{\eta}_{kl}), \\ \hat{\Omega}_A &:= \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{ir}; \hat{\theta}, \hat{\eta}_{kl})', \\ \hat{\Omega}_{\text{DK}} &:= \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \frac{K/L}{N_k T_l^2} \sum_{t \in S_l, r \in S_l} k\left(\frac{|t-r|}{M}\right) \sum_{i \in I_k, j \in I_k} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{jr}; \hat{\theta}, \hat{\eta}_{kl})', \\ \hat{\Omega}_{\text{NW}} &:= \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} k\left(\frac{|t-r|}{M}\right) \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{ir}; \hat{\theta}, \hat{\eta}_{kl})' .\end{aligned}$$

It is noted that the variance estimator under the cross-fitting is equivalent to estimating the variance in each sub-sample and then averaging across all sub-samples. Since K, L are fixed, the asymptotic analysis is done at the sub-sample level. The next theorem establishes the consistency of this variance estimator under the conventional small-bandwidth assumption.

Theorem 3.2 (Consistent Variance Estimator). *Assumptions AHK, AR, ND, DML1, DML2 hold for any*

¹¹For example, see Hansen, 2007, MacKinnon et al., 2021, Menzel, 2021, Chiang et al., 2022, Chiang et al., 2023a, Chiang et al., 2024, Chen and Vogelsang, 2024 among many others.

$P \in \mathcal{P}_{NT}$, and some $q > 4$ (defined in Assumption DML2), and $M/T^{1/2} = o(1)$. Then, as $N, T \rightarrow \infty$ and $N/T \rightarrow c$ where $0 < c < \infty$,

$$\hat{V}_{\text{CHS}} = V + o_P(1).$$

Theorem 3.2 can be seen as a generalization of the consistency result for the CHS variance estimator in Chiang et al. (2024) by allowing for the estimated nuisance parameters in the moment functions.

A remaining practical issue is that \hat{V} is not ensured to be positive semi-definite. It has been shown in Chen and Vogelsang (2024) that negative variance estimates happen with a non-trivial number of times under certain data-generating processes. Accordingly, an alternative two-term variance estimator was proposed in Chen and Vogelsang (2024). Following the same idea, I propose an alternative variance estimator by dropping the double-counting term $\hat{\Omega}_{\text{NW}}$:

$$\begin{aligned}\hat{V}_{\text{DKA}} &= \hat{A}^{-1} \hat{\Omega}_{\text{DKA}} \hat{A}^{-1'}, \\ \hat{\Omega}_{\text{DKA}} &= \hat{\Omega}_{\text{A}} + \hat{\Omega}_{\text{DK}}.\end{aligned}$$

The estimator is referred to as the DKA variance estimator because it is a sum of Driscoll-Kraay and Arellano variance estimators.¹² Similar approaches can be found in MacKinnon et al. (2021). It relies on the fact that the double-counting term is of small order asymptotically when the panel is two-way clustering. Similar to other two-term cluster-robust variance estimators, it has the computational advantage of guaranteeing positive semi-definiteness but at the cost of inconsistency in the case of no clustering or clustering at the intersection. For theoretical results and more detailed discussions on the trade-off between the ensured positive-definiteness and the risk of being too conservative/losing power, readers are referred to MacKinnon et al. (2021) and Chen and Vogelsang (2024).

Theorem 3.3 (Alternative Consistent Variance Estimator). *Under the same conditions as Theorem 3.2, we have, as $N, T \rightarrow \infty$ and $N/T \rightarrow c$ where $0 < c < \infty$,*

$$\hat{V}_{\text{DKA}} = \hat{V}_{\text{CHS}} + o_P(1).$$

Theorem 3.3 formally shows that the double-counting term is of small order under two-way clustering and it implies that the \hat{V}_{DKA} is also consistent for Ω under two-way clustering.

To conclude, in this section, I establish the inferential theory for the panel DML estimator, under high-level assumptions on the first-step estimator. It reveals that under the main set of assumptions considered in previous sections, the rate requirement is likely too stringent for any high-dimensional estimator under two-

¹²Note that, the DKA estimator defined in Chen and Vogelsang (2024) differs from the DKA estimator here by a constant term based on fixed-b asymptotic analysis. Such bias correction is not considered here since the fixed-b properties are not directly applicable in this setting. The conjecture is that the same form of bias correction can be applied here but formally establishing the fixed-b asymptotic results with the presence of estimated nuisance parameters is challenging and out of the scope of this paper, and so is left for future research.

way dependence. However, with an extra m -dependence condition, I show that the crude rate requirement is less stringent and can be achieved by the two-way cluster estimator proposed in Section 2. In the next section, I will study a special case of the semiparametric restriction model but consider the complication due to unobserved heterogeneity. I will demonstrate how to apply the results from this section and previous sections and discuss an extra subtle issue.

4. Partial Linear Model with Unobserved Heterogeneity

In this section, a partial linear model with non-additive unobserved heterogeneous effects is considered and I will illustrate how the proposed high-dimensional methods proposed in the previous two sections can be leveraged. The proposed toolkit is flexible enough to allow for models with instrumental variables used for identification, so I consider the following model: for $i = 1, \dots, N$ and $t = 1, \dots, T$,

$$Y_{it} = D_{it}\theta_0 + g(X_{it}, c_i, d_t) + U_{it}, \quad E[U_{it}|X_{it}, c_i, d_t] = 0, \quad (4.1)$$

where D_{it} is a low-dimensional vector of endogenous variables; g is an unknown function of potentially high-dimensional control variables X_{it} and unobserved heterogeneous effects (c_i, d_t) . For clearer presentation, D_{it} is treated as a scalar variable. In practice, D_{it} can contain some high-order terms and interactions with a low-dimensional vector of controls. If the lags or leads of D_{it} are considered to be exogenous, they can also be included in X_{it} . Doing so would not change the theory for estimation and inference but doing so would change the interpretation of θ_0 . Consider an excludable instrumental variable Z_{it} such that $E[Z_{it}U_{it}] = 0$, which gives the identifying moment condition.

To apply the estimation and inference methods proposed in previous sections, g is again assumed to be approximately sparse. However, it does not suffice since (c_i, d_t) are not observed. To deal with the unobserved heterogeneous effects that cause the endogeneity, I take a correlated random-effects approach through the generalized Mundlak device:

Assumption GMD (Generalized Mundlak Device). *For each $i = 1, \dots, N$ and $t = 1, \dots, T$,*

$$c_i = h_c(\bar{F}_i, \epsilon_i^c), \quad (4.2)$$

$$d_t = h_d(\bar{F}_t, \epsilon_t^d), \quad (4.3)$$

where $\bar{F}_i = \frac{1}{T} \sum_{t=1}^T F_{it}$, $\bar{F}_t = \frac{1}{N} \sum_{i=1}^N F_{it}$, $F_{it} := (D_{it}, X'_{it})'$; h_c and h_d are unknown functions; the stochastic errors $(\epsilon_i^c, \epsilon_t^d)$ are each a random draw from some unknown distribution.

To justify its use, we shall recall the idea of the conventional Mundlak device. Due to the correlation between (c_i, d_t) and the covariates, the endogeneity issue arises if we don't control for the unobserved heterogeneity. To explicitly model the correlation between the random effects and the covariates, Mundlak (1978) proposes an auxiliary regression between the random effects and the cross-sectional sample average

and shows that if the random effects enter the model linearly then the resulting estimator GLS estimator is equivalent to the common within-estimator. Wooldridge (2021) further shows that the equivalence relations exist among the POLS estimators resulting from the Mundlak device, within-transformation, and the fixed-effects dummies. Therefore, if the within-transformation and including fixed-effects dummies are sensible and commonly accepted ways of dealing with unobserved heterogeneity, then allowing the Mundlak regression to have a more flexible function form should also be sensible and more robust. A similar assumption is considered in Wooldridge and Zhu (2020).

For the rest of the analysis, (\bar{F}_i, \bar{F}_t) are treated as fixed. As both N and T diverge to ∞ , we can show (\bar{F}_i, \bar{F}_t) converge to some well-defined probability limits under regularity conditions introduced later. However, to incorporate the variation of (\bar{F}_i, \bar{F}_t) into the analysis when they enter the model in a non-additive way is highly non-trivial. This is similar to the fixed-effect approach where the unobserved effects are treated as random at first and the analysis is conditional on the realized values of the unobserved effects.

Under model 4.1, $g(X_{it}, c_i, d_t) = E[Y_{it} - D_{it}\theta_0 | X_{it}, c_i, d_t]$. We can rewrite 4.1 as follows:

$$Y_{it} = (D_{it} - g_D(X_{it}, c_i, d_t))\theta_0 + g_Y(X_{it}, c_i, d_t) + U_{it}.$$

where $g_D(X_{it}, c_i, d_t) := E[D_{it} | X_{it}, c_i, d_t]$ and $g_Y(X_{it}, c_i, d_t) := E[Y_{it} | X_{it}, c_i, d_t]$. Under Assumption GMD, $g_D(X_{it}, c_i, d_t)$ and $g_Y(X_{it}, c_i, d_t)$ can be rewritten as compound functions

$$\begin{aligned} g_D^*(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d) &:= g_D(X_{it}, h_c(\bar{F}_i, \epsilon_i^c), h_d(\bar{F}_t, \epsilon_t^d)) \\ g_Y^*(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d) &:= g_Y(X_{it}, h_c(\bar{F}_i, \epsilon_i^c), h_d(\bar{F}_t, \epsilon_t^d)) \end{aligned}$$

As in Section 2, the nuisance functions g_D^* and g_Y^* are assumed to be well-approximated by a linear combination of a τ -th order polynomial transformation L^τ as follows:

$$g_D^*(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d) = L^\tau(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d)\eta_D + r_{it}^D \quad (4.4)$$

$$g_Y^*(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d) = L^\tau(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d)\eta_Y + r_{it}^Y \quad (4.5)$$

where (η_D, η_Y) are slope coefficients and (r_{it}^D, r_{it}^Y) are the approximation errors. Furthermore, we can define a vector of transformed regressors as

$$L_{1,it} = L^\tau(X_{it}, \bar{F}_i, \bar{F}_t),$$

and a vector of unobserved regressors as

$$L_{2,it} = L^\tau(X_{it}, \bar{F}_i, \bar{F}_t, \epsilon_i^c, \epsilon_t^d) \setminus L^\tau(X_{it}, \bar{F}_i, \bar{F}_t)$$

Let $(\eta_{D,1}, \eta_{D,2})$ be such that $\eta_D = \eta_{D,1} \cup \eta_{D,2}$ and $L^\tau(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d)\eta_D = L_{1,it}\eta_{D,1} + L_{2,it}\eta_{D,2}$; and $(\eta_{Y,1}, \eta_{Y,2})$ are defined in the same way. Under the sparse approximation and Assumption GMD, we can

rewrite model 4.1 as follows:

$$Y_{it} = (D_{it} - L_{1,it}\eta_{D,1} - L_{2,it}\eta_{D,2} - r_{it}^D)\theta_0 + L_{1,it}\eta_{Y,1} + L_{2,it}\eta_{Y,2} + r_{it}^Y + U_{it},$$

By defining a new error term $V_{it} := (L_{2,it} - E[L_{2,it}]) (\eta_{Y,2} - \eta_{D,2}\theta_0) + U_{it}$, a new approximation error $r_{it} = r_{it}^Y + r_{it}^D\theta_0$, an observable vector $f_{it} := (L_{1,it}, 1)'$ with dimension denoted by p , and nuisance vectors $\beta_0 := (\eta_{Y,1}, E[L_{2,it}]\eta_{Y,2})$, $\pi_0 := (\eta_{D,1}, E[L_{2,it}]\eta_{D,2})$, we can rewrite the model above as

$$Y_{it} = (D_{it} - f_{it}'\pi_0)\theta_0 + f_{it}'\beta_0 + r_{it} + V_{it}. \quad (4.6)$$

Observing $E[L_{2,it}|X_{it}, \bar{F}_i, \bar{F}_t] = 0$ due to the independence between $(\epsilon_i^c, \epsilon_t^d)$ and $(X_{it}, \bar{F}_i, \bar{F}_t)$, it follows that $E[V_{it}|X_{it}, \bar{F}_i, \bar{F}_t] = 0$ and so $E[f_{it}'V_{it}] = 0$. Noticeably, in this case, the parameters associated with the unobservables $L_{2,it}$ can be arbitrarily non-sparse.

Given $E[Z_{it}U_{it}]$ and the independence between Z_{it} and $(\epsilon_i^c, \epsilon_t^d)$, we have the identifying moment condition $E[Z_{it}V_{it}] = 0$. Let ζ_0 be the linear projection parameter of Z_{it} onto f_{it} and let V_{it}^Z be the corresponding linear projection errors. By Chernozhukov et al., 2018a, (2.18), the near-Neyman orthogonal function is given by:

$$\psi(W_{it}; \theta_0, \eta_0) := (Z_{it} - f_{it}'\zeta_0)(Y_{it} - f_{it}'\beta_0 - (D_{it} - f_{it}'\pi_0)\theta_0). \quad (4.7)$$

where $W_{it} = (Y_{it}, D_{it}, X_{it}, Z_{it}, U_{it}, c_i, d_t)$ and $\eta_0 = (\zeta_0', \beta_0', \pi_0')'$. Define $U_{it}^Y = Y_{it} - E[Y_{it}|X_{it}, c_i, d_t]$ and $U_{it}^D = D_{it} - E[D_{it}|X_{it}, c_i, d_t]$. Then we can write

$$\begin{aligned} Y_{it} &= g_Y^*(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d) + U_{it}^Y = f_{it}'\beta_0 + r_{it}^Y + V_{it}^Y, \quad V_{it}^Y := (L_{2,it} - E[L_{2,it}])\eta_{Y,2} + U_{it}^Y, \\ D_{it} &= g_D^*(X_{it}, \bar{F}_i, \epsilon_i^c, \bar{F}_t, \epsilon_t^d) + U_{it}^D = f_{it}'\pi_0 + r_{it}^D + V_{it}^D, \quad V_{it}^D := (L_{2,it} - E[L_{2,it}])\eta_{D,2} + U_{it}^D. \end{aligned}$$

Since $E[V_{it}^Y|X_{it}, \bar{F}_i, \bar{F}_t] = E[V_{it}^D|X_{it}, \bar{F}_i, \bar{F}_t]$, we have $E[f_{it}'V_{it}^Y] = E[f_{it}'V_{it}^D] = 0$. And by definition of the linear projection, we have $E[f_{it}'V_{it}^Z] = 0$. Therefore, we can apply the proposed (post) two-way cluster LASSO to obtain estimates for η_0 . The estimator $\hat{\theta}$ is then obtained by solving the sample analog of $E[\psi(W_{it}; \theta_0, \eta_0)] = 0$ with η_0 replaced by the first-step estimates.

Assumption REG-P (Regularity Conditions for the Partial Linear Model). (i) $\log(p/\gamma) = o(T^{1/6}/\log T)$ and $p = o(T^{7/6}\log T)$.

- (ii) $[E(a_{i,j})^2]^{1/2}/[E(a_{i,j})^3]^{1/3} = O(1)$ for $j = 1, \dots, p$.
- (iii) For all $r \geq 0, m \geq 1$, $E[\sum_{t=r}^{r+m} f_{it,j}V_{it}^t]^2 \geq \mu^2 m$ for all j and $t = Y, D, Z$.
- (iv) For some $s > 1, \delta > 0$, $E[|Y_{it}|^{4(1+\delta)}] < \infty$, $E[|D_{it}|^{4(1+\delta)}] < \infty$, $E[|r_{it}^Y|^{4(1+\delta)}] < \infty$, $E[|r_{it}^D|^{4(1+\delta)}] < \infty$, $E[|f_{it,j}|^{8(s+\delta)}] < \infty$, $E[|V_{it}^t|^{8(s+\delta)}] < \infty$ for all j and $t = Y, D, Z$.
- (v) Either $\lambda_{a,j} := [E(a_{i,j}^2)]^{1/2} > 0$ or $\lambda_{g,j} := [\sum_{\ell=-\infty}^{\infty} E[g_{t,j}g_{t+\ell,j}]]^{1/2} > 0$.
- (vi) $E[(Z_{it} - f_{it}'\zeta_0)(D_{it} - f_{it}'\pi_0)]$ is non-singular.

(vii) $\|E[(V_{it}^t)^2|f_{it}]\|_{P,\infty} < \infty$, $\|E[(r_{it}^t)^2|f_{it}]\|_{P,\infty} < \infty$, for $t = Y, D$.

This set of regularity conditions follows from the assumptions needed for both two-way cluster-LASSO and the panel-DML inference. The only extra condition is Assumption REG-P(vii) which states that the conditional second moments of the stochastic errors and the approximation errors are uniformly bounded. So even if V_{it}^t and f_{it} are not independent, we can treat the conditional second moments as some bounded constants, which is useful when we employ cross-fitting and use the properties of the second moments of the error terms to relax the rate requirement for the nuisance estimation.

Corollary 4.1. *Suppose, for $P = P_{NT}$ for each (N, T) , $W_{it} = (Y_{it}, D_{it}, X_{it}, Z_{it}, U_{it}, c_i, d_t)$, and $\psi(W_{it}; \theta_0, \eta_0)$ defined in 4.7: (i) Assumptions GMD, REG-P, AHK, AR, and ND hold; (ii) Assumption SE holds with $M_f = E_{kl}[f_{it}f_{it}']$ for each (k, l) ; (iii) the sparse approximation in 4.4 and 4.5 holds with $s = o\left(\frac{\sqrt{N}}{\log(p/\gamma)}\right)$, $\|r_{it}^t\|_{N_k T_l, 2} = O_P\left(\sqrt{\frac{s}{N \wedge T}}\right)$. Then, as $N, T \rightarrow \infty$ and $N/T \rightarrow c$ where $0 < c < \infty$,*

$$\sqrt{N \wedge T}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V)$$

where $V := A_0^{-1} \Omega A_0^{-1}$, $A_0 := E_P[(Z_{it} - f_{it}' \zeta_0)(D_{it} - f_{it}' \pi_0)]$ and $\Omega := \Lambda_a \Lambda_a' + c \Lambda_g \Lambda_g'$.

Corollary 4.1 is an application of Theorem 2 and Theorem 3.1. Note that the sparsity condition is stronger than the one for LASSO estimation to be consistent. This is because of the approximation error and the form of the orthogonalized moment condition that requires the first-steps to converge in certain rate for valid inference. In the scenarios when the approximation is exact and $\lambda'_{NT} = 0$ in Assumption DML2, a consistent nuisance estimate with convergence rate $o(1)$ in $L^2(P)$ norm would suffice.

5. Monte Carlo Simulation

In this section, we examine the performance of the panel DML estimation and inference procedure in a Monte Carlo simulation study. To focus on the performance of the panel DML procedure and the LASSO estimator, the DGPs considered in this section are free of correlated random effects. Firstly, I consider the following triangular model without approximation error, simplified from the partial linear model in Section 4:

$$\begin{aligned} \text{Linear Model : } Y_{it} &= D_{it}\theta_0 + X_{it}\beta_0 + U_{it}, \\ D_{it} &= X_{it}\pi_0 + V_{it}, \end{aligned}$$

where $\theta_0 = 1/2$ and $\beta_0 = \pi_0 = a(1, 1, \dots, 1, 0, \dots, 0)'$ are p -dimensional parameter vectors where the first s entries are 1 and the rest of the elements are 0; a is a constant that controls the relevance of the covariates.

Secondly, I also consider the case where the true nuisance function form is unknown but it is smooth enough so it can be well-approximated by a linear combination of polynomially transformed variables:

$$\begin{aligned}\textbf{Nonlinear Model : } Y_{it} &= D_{it}\theta_0 + \frac{X_{it}\beta_0}{1 + (X_{it}\beta_0)^2} + U_{it}, \\ D_{it} &= \frac{X_{it}\pi_0}{1 + [\exp(X_{it}\pi_0)]^{-1}} + V_{it},\end{aligned}$$

where the parametrization is the same as DGP(i). For DGP(ii), we pretend the nuisance functions of X_{it} are unknown, but, since they are sufficiently smooth functions of X_{it} with bounded derivatives, it can be shown by Taylor expansion that they can be well-approximated (in the sense of Assumption ASM) by a polynomial series of sufficiently large order.

To feature in the two-way dependence in $V_{it}U_{it}$ as well as $X_{it}U_{it}$ and $X_{it}V_{it}$, (X_{it}, U_{it}, V_{it}) are generated by the underlying components as follows: for each $j = 1, \dots, p$,

$$\begin{aligned}\textbf{Additive Components : } X_{it,j} &= w_1\alpha_{i,j} + w_2\gamma_{t,j} + w_3\varepsilon_{it,j}, \\ U_{it} &= w_1\alpha_i^u + w_2\gamma_t^u + w_3\varepsilon_{it}^u, \\ V_{it} &= w_1\alpha_i^v + w_2\gamma_t^v + w_3\varepsilon_{it}^v,\end{aligned}$$

where the components $\alpha_i^u, \alpha_i^v, \varepsilon_{it}^u, \varepsilon_{it}^v, \alpha_{i,j}, \gamma_{t,j}$ are each random draws from a uniform distribution with support $(-\sqrt{3}, \sqrt{3})$ for each j ; $\varepsilon_{it} = (\varepsilon_{it,1}, \dots, \varepsilon_{it,p})'$ is a random draw from a joint normal distribution with mean 1 and variance-covariance matrix equal to $\iota^{[j-k]}$, $\iota \in [0, 1)$, in the (j, k) 's entry; The components γ_t^u, γ_t^v each follow a AR(1) process with the coefficient equal to ρ and the initial values randomly drawn from the normal distribution with mean 0 and variance $1 - \rho^2$ for some $\rho \in [0, 1)$. The weights (w_1, w_2, w_3) are non-negative with $w_1 + w_2 + w_3 = 1$.

In practice, it is common to apply a within-transformation for a linear model with additive unobserved heterogeneity. In that case, if the component structure is exactly as described above, then the within-transformation not only deals with the endogeneity due to the unobserved heterogeneity but also eliminates the two-way dependence introduced by the linear components. To illustrate it is not necessarily the case in general and verify the theory under a different scenario, I also consider a multiplicative component structure DGP that features two-way dependence in the moment function even after the within-transformation:

$$\begin{aligned}\textbf{Multiplicative Components : } X_{it,j} &= w_1\alpha_{i,j} + w_2\gamma_{t,j} + w_3\varepsilon_{it,j}, \\ U_{it} &= \frac{w_4}{c_p} \sum_{j=1}^p [\alpha_i^u \gamma_{t,j} + \alpha_{i,j} \gamma_t^u] + w_5\varepsilon_{it}^u, \\ V_{it} &= \frac{w_4}{c_p} \sum_{j=1}^p [\alpha_i^v \gamma_{t,j} + \alpha_{i,j} \gamma_t^v] + w_5\varepsilon_{it}^v,\end{aligned}$$

where the components are generated the same way as the Linear Components. The weights $(w_1, w_2, w_3, w_4, w_5)$ are non-negative with $w_1^2 + w_2^2 + w_3^2 = 1$ and $w_4^2 + w_5^2 = 1$. c_p is a scaling factor that ensures the sums of multiplicative components in both U_{it} and V_{it} are variance 1.

The multiplicative components construction here is a generalization of the example in Chiang et al. (2024) where it is used to illustrate that the two-way within-transformation of the original linear panel model may not eliminate the underlying components. To see why $U_{it}V_{it}$ features a component structure, we can expand the product and observe that it includes terms like $\alpha_i^u \alpha_i^v \gamma_{t,j}^2$ for $j = 1, \dots, p$ whose conditional expectations given $\alpha = (\alpha_i^u, \alpha_i^v, \alpha_{i,1}, \dots, \alpha_{i,p})$ are $\alpha_i^u \alpha_i^v$ since $\gamma_{t,j}$ has variance 1 and is independent of α . Likewise, the product also includes terms like $\gamma_t^u \gamma_t^v \alpha_{i,j}^2$ whose conditional expectations given $\gamma = (\gamma_t^u, \gamma_t^v, \gamma_{t,1}, \dots, \gamma_{t,p})$ are $\gamma_t^u \gamma_t^v$. We can also show that $X_{it,j}U_{it}$ and $X_{it,j}V_{it}$ possess a components structure in a similar way. Importantly, these underlying common factors do not introduce endogeneity as they may seem to.

The simulation study examines the Monte Carlo bias(Bias), standard deviation (SD), mean square error (MSE), and coverage probability of estimators for θ_0 . All estimations are based on the orthogonal moment condition. The comparison will be among procedures with and without cross-fitting. The first-step estimations will be based on the POLS estimator (if feasible), the heteroskedasticity-robust LASSO from Belloni et al. (2012), the square-root LASSO from Belloni et al. (2011), the cluster-robust LASSO from Belloni et al. (2016), and the two-way cluster-LASSO with CHS-type and DKA-type feasible penalty weights. The CHS-type and DKA-type variance estimators (different formulas for estimations with and without cross-fitting) will be used to obtain sample coverage probabilities. In some unreported simulations, I also compare CHS/DKA type variance estimators with Eicker-Huber-White type estimators in Chernozhukov et al. (2018a) for random sampling data and Cameron-Galbach-Miller type estimator from Chiang et al. (2022) for multiway clustered data. Since it is well-known that inference based on variance estimators not sufficiently accounting for the dependence would cause over-rejection, it is omitted from the current version. Theoretically, among the candidates, only the approaches using cross-fitting and with the first step through the two-way cluster-LASSO estimator are guaranteed to produce asymptotically normal estimators and have correct size when CHS/DKA type variance estimators are used for inference. As we will see, cross-fitting indeed improves the sample coverage probability across all approaches with different first-step estimators but approaches without using cross-fitting also perform reasonably well when the model is less dense.

The simulation results are based on 500 Monte Carlo replications. It is a relatively small number of replications but it is necessitated by the high computational cost of multiple high-dimensional estimation and inference procedures. The estimation is based on the orthogonal moment condition given as follows by 4.7 with $Z_{it} = D_{it}$, $f_{it} = X_{it}$, $\zeta_0 = \pi_0$. Results are obtained across DGPs varied by the sample sizes (N, T) , the dimensions of covariates p , the number of non-zero slope coefficients s , the other sparsity parameter b , the common coefficient a , the multicollinearity parameter ι and the temporal correlation parameter ρ . For the panel DML inferential procedure with cross-fitting, the tuning parameters (K, L) , the number of cross-fitting blocks, needs to be chosen. For the two-way cluster-LASSO estimation, the sufficiently large constant C_λ , the $o(1)$ term γ , and the number of iterations m for the feasible weights are needed. For both variance

estimation and feasible weight estimation, bandwidth parameters M of the Bartlett kernel are required. I use the min-MSE rule from Andrews (1991) for both purposes. For a generic scalar score v_{it} , the formula is given as follows:

$$\hat{M} = 1.8171 \left(\frac{\hat{\rho}^2}{(1 - \hat{\rho}^2)^2} \right)^{1/3} T^{1/3} + 1,$$

where $\hat{\rho}$ is the OLS estimator from the regression $\bar{v}_t = \rho \bar{v}_{t-1} + \eta_t$ where $\bar{v}_t = \frac{1}{N} \sum_{i=1}^N \hat{v}_{it}$. For variance estimation, $\hat{v}_{it} = \hat{U}_{it} \hat{V}_{it}$; For feasible weights estimation, $\hat{v}_{it} = x_{it} \hat{U}_{it}$ or $\hat{v}_{it} = x_{it} \hat{V}_{it}$ where x_{it} is a generic scalar regressor.

Note: Simulation results are based on 500 replications. Tuning parameters: $(K, L) = (4, 8)$, $C_\lambda = 2.1$, $m = 2$, and $\gamma = 0.1/\log(p \vee N \vee T)$. H: heteroskedastic-LASSO; R: square-root-LASSO; C: cluster-LASSO; TW: two-way cluster-LASSO with CHS and DKA labeled for the feasible penalty weights. Post-LASSO POLS is performed in all first steps. Based on the sample correlation with the outcome, the 5 most relevant regressors are used to obtain the initial feasible penalty weights for all three LASSO approaches. Nominal coverage probability: 0.95.

Table 5.1 presents a set of baseline results that are obtained for a reasonably large number of regressors ($p = 200$) among which 5 are associated with non-zero slope coefficients. The number of covariates is much larger than either cross-sectional or temporal dimensions. Still, the number of non-zero coefficients can be regarded as a small order of the sample sizes, satisfying the sparsity condition. In the first step, model selections are done using different LASSO approaches reported in the second column. The number of

selected regressors for both Y and D are reported in the third and fourth columns. First, we take a look at the rows without using cross-fitting. It is shown that the proposed two-way cluster-LASSO, either performed with CHS or DKA feasible weights, selects almost perfectly while other LASSO approaches all over-select to a different degree. Among the LASSO-based approaches, the proposed methods suffer from the least finite sample bias. However, the proposed methods have slightly larger variability in terms of Monte Carlo SD and RMSE. For sample coverage, both CHS- and DKA-type variance estimators are used for all methods. In terms of variance estimation and inference, all high-dimensional methods suffer from under-coverage slightly while the proposed methods have the least size distortion. This can result from a strong serial correlation in the time effects ($\rho = 0.75$) and can also be explained by the fact that under high-dimensionality and two-way cluster dependence, the asymptotic normality is not guaranteed without cross-fitting, as discussed in Section 2. Surprisingly, POLS performs slightly better than high-dimensional methods for a reasonably high-dimensional model. However, as we will see later, it is not true anymore when the dimension of covariates grows further.

Table 5.2: Linear Model with Additive Components

Based on the sample correlation with the outcome, the 5 most relevant regressors are used to obtain the initial feasible penalty weights for all three LASSO approaches. Nominal coverage probability: 0.95.

When cross-fitting is employed, all methods have witnessed a significant improvement in terms of sample coverage. This is particularly true for LASSO-based methods that are not designed for dependent data, which is not predicted by the theory. As a cost, we can see from the increased Monte Carlo SD that there is a

loss of efficiency by doing cross-fitting, as expected. It is also worth emphasizing that the CHS- and DKA-type variance estimators designed for cross-fitting approaches play an important role in the desirable sample coverage. In some unreported simulations, it is shown that inference based on the cross-fitting variance estimators proposed in Chernozhukov et al. (2018a) and Chiang et al. (2022) suffer from severe under-coverage. This is not surprising but the implication is more subtle: while two-way dependence potentially affects both estimation and inference, its negative impact on the inference is more salient.

As the dimension of the covariates is as large as the overall sample size, a different pattern is revealed. Table 5.2 considers the same DGP as Table 5.1 except that the dimension p now increases to 800, slightly smaller than the sample size 900. In principle, we can compare a case with the dimension of covariates larger than the sample size, but then it is not possible to compare the results based on the POLS first-steps. First, we compare the results without cross-fitting. The simulation results demonstrate that the methods based on the POLS first-steps with no selection and those based on the existing LASSO approaches with over-selection all suffer from severe under-coverage. The proposed methods, in contrast, continue to select almost perfectly regardless of the increased number of irrelevant regressors. Again, when cross-fitting is performed, there is a significant improvement across all approaches in terms of the sample coverage. This is expected: as shown in the proof of Theorem ??, the error term R_{NT}^2 contains terms such as $V_{it}^D(\beta_0 - \tilde{\beta})$ that are not mean 0 and may not vanish fast enough; this is more severe when no selection or inconsistent selection is performed in the first stage. Through the proper cross-fitting scheme, such terms are conditionally mean-zero even with over-selection. Such property of cross-fitting methods is thus translated into better coverages across all approaches considered here.

Note: Simulation results are based on 500 replications. Tuning parameters: $(K, L) = (4, 8)$, $C_\lambda = 2.1$, $m = 5$, and $\gamma = 0.1/\log(p \vee N \vee T)$. H: heteroskedastic-LASSO; R: square-root-LASSO; C: cluster-LASSO; TW: two-way cluster-LASSO with CHS and DKA labeled for the feasible penalty weights. Post-LASSO POLS is performed in all first steps. Based on the sample correlation with the outcome, the 5 most relevant regressors are used to obtain the initial feasible penalty weights for all three LASSO approaches. Nominal coverage probability: 0.95.

We have seen the case with exact sparsity in Tables 5.1 and 5.2. As argued in the theory, the proposed estimation and inference procedures are also valid under approximate sparsity. In Table 5.3, we consider a case where 10 observable control variables are considered by the researcher while only 5 of those are relevant. Those 5 relevant controls enter the model through unknown but smooth nuisance functions as described above. The researchers are not aware of the irrelevance of the other five controls and neither do researchers have knowledge of the nuisance function forms. However, the smoothness allows for the approximation of the nuisance function using polynomials series. In particular, we use the 3rd-order polynomial transformation of the 10 observable controls for approximation. Due to bounded derivatives of the smooth nuisance functions and the irrelevance of some of the controls, the sparse approximation is valid. As is shown in Table 5.3, compared to previous sets of results, the advantage of the proposed methods is not obvious in this case. From the number of selected regressors and the Monte Carlo SD across all methods, it seems the dependence is not as strong as in previous DGPs. Given the small number of Monte Carlo replications, the differences in sample coverage probabilities across different approaches are not really distinguishable. On the other hand, the improvement made by the use of the cross-fitting remains significant.

	TW LASSO DKA	5.1	4.8	0.023	0.154	0.155	92.4	95.4

Note: Simulation results are based on 500 replications. Tuning parameters: $(K, L) = (4, 8)$, $C_\lambda = 2.1$, $m = 2$, and $\gamma = 0.1/\log(p \vee N \vee T)$. H: heteroskedastic-LASSO; R: square-root-LASSO; C: cluster-LASSO; TW: two-way cluster-LASSO with CHS and DKA labeled for the feasible penalty weights. Post-LASSO POLS is performed in all first steps. Based on the sample correlation with the outcome, the 5 most relevant regressors are used to obtain the initial feasible penalty weights for all three LASSO approaches. Nominal coverage probability: 0.95.

Lastly, I use the multiplicative components to generate two-way cluster dependence and compare the results in Table 5.4. There are two main differences compared to previous results. First, the two-way dependence is present but relatively weak. In some unreported simulation results using variance estimators not accounting for two-way dependence, all methods suffer from under-coverage issues, implying the presence of two-way dependence. Additionally, we can see the over-selection problem is almost not present for heteroskedasticity-LASSO, square-root-LASSO, and cluster-LASSO, also indicating the dependence is quite weak. Secondly, notice that the two-way cluster LASSO with CHS-type penalty weights over-selects, in a more severe way than existing approaches not accounting for two-way dependence. Further examination of the issue reveals that it is due to the finite-sample bias of the HAC-type formula: it is well known that HAC-type variance estimators are not guaranteed to be positive-semi definite. Under certain DGPs, the HAC-type estimator is more likely to be negative or close to 0, causing large finite sample bias in variance estimation. This is likely to be the case here. Indeed, some penalty weights estimated using the CHS formula are negative and replaced by 0. There are other finite sample adjustments available but in general, it is a disadvantage for the CHS-type penalty weights. The DKA-type feasible weights are guaranteed to be positive and it has been shown in the literature that the two-term formulas for variance estimation tend to have better

finite sample performance (Chen and Vogelsang (2024)). However, it is also well-known that the two-term formulas for variance estimation suffer from an overestimation problem when the true DGP is i.i.d over both clusters or is only clustered at the intersection of the two clusters (MacKinnon et al. (2021)). In practice, it is very rare to encounter panel data not featuring any dependence across space or time. As a result, it is in general recommended to use the DKA-type formula for both penalty weights and variance estimation.

6. Empirical Application

In this section, I re-examine the effects of government spending on the output of an open economy following the framework of Nakamura and Steinsson (2014). It is one of the most cited empirical-macro papers on the American Economic Review and it investigates one classic quantity of interest in economics: the government spending multiplier. The question is can we improve on the estimation and inference through more robust and flexible methods? As I will show, it is made possible by the proposed toolkit in this paper.

This framework utilizes the regional variation in military spending in the US to estimate the percentage increase in output that results from the increase of government spending by 1 percent of GDP, i.e. government spending multiplier. It is referred to as the "open economy relative multiplier" because this framework takes advantage of uniform monetary and tax policies across the regions in the US to difference-out their effects on government spending and output. The parameter of interest is a scalar and the baseline model does not even need a control for identification, so why is the high-dimensionality relevant here? As it will be revealed very soon, indeed, the high dimensionality from heterogeneity and flexible modeling can be hidden in settings to which researchers don't usually relate high dimensionality.

Due to the endogeneity in the variation of the regional military procurement, Nakamura and Steinsson (2014) achieves identification through an instrumental variable (IV) approach. As argued by the authors, the national military spending is largely determined by geopolitical events so it is likely exogenous to the unobserved factors of regional military spending and it affects the regional military spending disproportionately. In other words, the identifying assumption is that the buildups and drawdowns in national military spending are not due to unbalanced military development across regions. Based on this observation, a share-shift type IV is considered and the share is estimated by regressing the regional military spending on the national military spending allowing for region-specific constant slope coefficients.¹³ To focus on the main idea, the shares are taken as given and the resulting instrument variable is treated as observable instead of generated regressors to avoid further complication.

In this paper, I extend the linear model with additive unobserved heterogeneous effects to a partial linear model with non-additive unobserved heterogeneous effects. Let D_{it} be the percentage change in per capita regional military spending in state i and time t and Z_{it} be the IV. Specifically, the baseline model from the

¹³All quantities, unless specifically defined, are in terms of two-year growth rate of the real per capita values. Per capita is in terms of total population. Nakamura and Steinsson (2014) also presents results when per capita is calculated using the working age population as a robustness check.

original study and the one from this paper differ as follows:

The baseline linear Model :

$$Y_{it} = \theta_0 D_{it} + \pi_i W_t + c_i + d_t + U_{it}.$$

The partial Linear Model :

$$Y_{it} = \theta_0 D_{it} + g(X_{it}, W_t, c_i, d_t) + U_{it}.$$

where θ_0 is the parameter of interest, i.e. the true multiplier; X_{it} and W_t are exogenous control variables with the latter being only time-varying; π_i are non-random unit specific slope coefficients of W_t ; (c_i, d_t) are unobserved heterogeneous effects. In the original study, the linear model is estimated by the two-stage least square (2SLS) with two-way fixed effects. In the extended model, I model the unobserved heterogeneous effects as correlated random effects and take a sparse approximation approach for the infinite-dimensional nuisance parameters as in Section 4. Specifically, c_i is assumed to be a function of (\bar{D}_i, \bar{X}_i) and d_t is assumed to be a function of $(\bar{D}_t, \bar{X}_t, W_t)$. Then, through sparse approximation, the feasible (near) Neyman-orthogonal moment function is given by

$$(Z_{it} - f_{it}\zeta_0) (Y_{it} - f_{it}\beta_0 - \theta_0 (D_{it} - f_{it}\pi_0))$$

where $f_{it} = (L^\tau(X_{it}, W_t, \bar{D}_i, \bar{D}_t, \bar{X}_i, \bar{X}_t), 1)$ and (β, π, ζ) are associated slope coefficients defined the same way as in ??-??.

In the original study, W_t are not included in the baseline model. In the alternative specifications, W_t is chosen as the real interest rate or the change in national oil price. These two variables are never included together in the original study. Note that allowing the unit-specific slope coefficients for controls generates many nuisance parameters: with 51 state groups¹⁴, one control would increase 51 parameters and two controls would generate 102 parameters, given no interactions or higher order terms. With a sample size less than 2000, the high dimensionality in nuisance parameters could result in a noisy estimate of θ_0 . In this paper, to obtain a more precise estimate and make the excludability assumption of the IV to be more plausible, besides the controls from the original study, I also consider additional controls. For X_{it} , I include the change in state population. As is shown in Table 3 of Nakamura and Steinsson (2014), the state population is likely not affected by the treatment (the regional military spending), so it is immune to the "bad control" problem¹⁵; But it could affect the treatment and the outcome. By considering more flexible function forms and additional exogenous control variables, the excludability condition of the instruments is more plausible. On the other hand, the high-dimensionality arose from the flexible function form and the unobserved hetero-

¹⁴The regions in this analysis are defined by the states. Nakamura and Steinsson (2014) also presents results on regions as clusters of states.

¹⁵Angrist and Pischke, 2009, Frölich, 2008, and Chen and Kim, 2024 provide detailed discussions on when endogenous control pollute the identification/estimation and when they are innocuous.

ogeneity necessitates the use of high-dimensional selection methods. Moreover, state-level yearly variables of those macroeconomic characteristics are often considered to be cluster-dependent in both space and time groups due to correlated time shocks and state-unobserved factors. These concerns justify the use of robust estimation and inference methods proposed in this paper.

The data is available through Nakamura and Steinsson (2014). It is a balanced (after trimming) state-level yearly panel data with 51 states from 1971-2005 years. The military spending data is collected from the electronic database of DD-350 military procurement forms of the US Department of Defense. The state output is measured by state DGP collected from the US Bureau of Economics Analysis (BEA). The state population data is from the Census Bureau. Data on oil prices is from West Texas Intermediate. The Federal Funds rate is from the FRED database of the St. Louis Federal Reserve. The state inflation measures are constructed from several sources. For more details on data construction, readers are referred to Nakamura and Steinsson (2014).

	Yes	Yes	Yes	POLS	1.36	0.43	0.56

Note: Standard errors and feasible penalty weights are calculated with the truncation parameter M chosen by the min-MSE rule given in Section 5.

Table 6.1 provides benchmark results for the original model with different choices of control variables. All estimates (columns 6 and 9) of are given by 2SLS with two-way fixed effects and the standard errors (s.e.) are calculated using CHS and DKA formulas given in Section 4. The estimates of the multiplier are matched with those given in Nakamura and Steinsson (2014) with significant differences in the standard errors. It is because the variance estimates here account for the potential two-way dependence while the variance estimator used in Nakamura and Steinsson (2014) assumes cross-sectional independence.

The main comparisons are done in Tables 6.2 and 6.3. In Table 6.2, no cross-fitting is performed in the first stage. The number of parameters associated with regressors generated by polynomials transformations are reported in column (4) and the number of selected parameters associated with Z are reported in column (6)¹⁶. Overall, with more controls and the polynomial transformation of the observables, the standard errors are generally larger than those in 6.1. With no transformations of the original regressors, the estimates obtained by four different methods are similar and they are consistent with the baseline results. It is noticeable

¹⁶Across all first-step LASSO approaches, more parameters associated with Z are selected compared to those associated with Y and X . The difference in the LASSO selection is less evident for Y and X while the pattern is similar.

				CR LASSO	6	0.97	0.65	0.80
				TW LASSO DKA	5	1.47	0.61	0.77

Note: The tuning parameters are chosen as $m = 10$, $C_\lambda = 2.1$, $\gamma = 0.1/\log(p \vee N)$. The control variables and the Mundlak sample averages (X_{it} , W_t , \bar{D}_i , \bar{D}_t , \bar{X}_i , \bar{X}_t) are used to obtain the initial feasible penalty weights for all three LASSO approaches. Number of predictors generated by the polynomial transformation and the number of selected predictors for Z are reported in columns (4) and (6). Standard errors and feasible penalty weights are calculated with the truncation parameter M chosen by the min-MSE rule given in Section 5.

that the proposed approach TW LASSO using the DKA-type penalty weights achieves an estimate that is consistent with the baseline results and has the least variability. As the flexibility and number of nuisance parameters increase with the higher-order polynomial transformations, the number of selected regressors increases across all methods. While the standard errors of most approaches climb become larger and the estimates deviate from the baseline results, the proposed approach remains less noisy. This indicates that many higher-order polynomials included in the extended model for robustness in the function form may not matter that much but sorely contribute to the noise; while the existing approaches tend to over-select those terms under potential two-way dependence, the proposed method is robust against over-selection.

For more robustness in inference, as is shown in both theoretical and simulation results, I further consider different methods implemented with cross-fitting in Table 6.3¹⁷. It shows a similar pattern as in Table 6.2: The variability of different methods increases as the model approximated by higher-order polynomial series, except for the proposed approach which witnesses more accuracy as the approximation is made more flexible. What's going on here could be potential nonlinearity in the true model unknown to the researcher. When no transformation or the 2nd-order polynomial transformation is used, a limited amount of nonlinearity is captured in the misspecified model. With the 3rd-order polynomial approximation, while the nonlinearity might

¹⁷Due to smaller samples in the first step and multicollinearity among the polynomial terms, methods based on the POLS first-step is too noisy and so they are omitted for comparison here.

				TW LASSO DKA	6.0	1.09	1.18	1.46

Note: The tuning parameters are chosen as $(K, L) = (4, 8)$, $m = 10$, $C_\lambda = 2.1$, $\gamma = 0.1 / \log(p \vee N \vee T)$. The control variables and the Mundlak sample averages $(X_{it}, W_t, \bar{D}_i, \bar{D}_t, \bar{X}_i, \bar{X}_t)$ are used to obtain the initial feasible penalty weights for all three LASSO approaches. Number of predictors generated by the polynomial transformation and the average (over cross-fitting sub-samples) number of selected predictors for Z are reported in columns (4) and (6). Standard errors and feasible penalty weights are calculated with the truncation parameter M chosen by the min-MSE rule given in Section 5.

be captured by all three methods in comparison, as revealed by the increased number of selected regressors, the proposed two-way cluster LASSO achieves that with fewer and likely more accurate selections. Unfortunately, although the cross-fitting approach is asymptotically valid and has better size control as shown in the simulation, it is in the cost of efficient loss, as told by the larger standard errors.

7. Conclusion and Discussion

The inferential theory for high-dimensional models is particularly relevant in panel data settings where the modeling of unobserved heterogeneity commonly leads to high-dimensional nuisance parameters. This paper enriches the toolbox of researchers in dealing with high-dimensional panel models. Particularly, I propose a package of tools that deal with the estimation and inference in high-dimensional panel models that feature in two-way cluster dependence and unobserved heterogeneity. I first develop a weighted LASSO approach that is robust to two-way cluster dependence in the panel data. As is shown in the asymptotic analysis of the two-way cluster LASSO, the convergence rates are quite slow due to the cluster dependence, making it challenging for inference purposes. However, by utilizing a cross-fitting method designed for a two-way clustered panel, the rate requirement for the first step can be substantially relaxed, making the proposed two-way cluster-LASSO a valid first-step estimator for inference purposes in a high-dimensional semiparametric model. Individually, both the two-way cluster-LASSO and the cross-fitting can be of independent interest; Together, they extend the DML approach to panel data settings. Furthermore, I study the subtle issues of cross-fitting and unobserved heterogeneity in panel models and provide strategies under various scenarios.

The estimation and inferential theory are empirically relevant. I illustrate the proposed approaches in

an empirical example and exemplify that high-dimensionality can be hidden in questions not traditionally considered high-dimensional. In practice, when the question is naturally high-dimensional and answered by panel data, then there is no reason not to apply the approaches in this paper. When the questions are originally not high-dimensional, it is reasonable to start with a simple model as a baseline and then extend it to a more general and flexible model for a robustness check.

While both theoretical and simulation results support the proposed approaches, some limitations remain in certain scenarios. First, the Mundlak device and, in general, many other approaches for dealing with unobserved heterogeneity are not compatible with the cross-fitting schemes due to the dependence introduced by the full history of the data that is used for modeling the unobserved heterogeneous effects. On the other hand, it is generally not feasible to establish the inferential theory without cross-fitting in high-dimensional semi-parametric models. In that sense, the cross-fitting approach is naturally limited in use for panel data models. Secondly, the feasible penalty weight estimation is highly non-trivial due to two-way cluster dependence and high dimensionality. The asymptotic analysis of the two-way cluster LASSO relies on high-level assumptions on the feasible penalty weights. Even though the iterative feasible weights estimation possesses desirable finite sample properties among the scenarios considered in the Monte Carlo simulation, there are many subtle issues that are lack of theoretical guarantee. A devoted exploration of such issues requires a more comprehensive treatment and is another important direction of future research.

Appendix A

Proof of Theorem 2.1. In the proof, we will show L1 and L2 convergence rates for $\hat{\zeta}$. We will first show the regularization event in terms of the infeasible penalty weights ω as defined in 2.8. Due to the AHK representation as in Assumption AHK, we can decompose $f_{it,j}V_{it}$ as $f_{it,j}V_{it} = a_{i,j} + g_{t,j} + e_{it,j}$ where $a_{i,j} := E[f_{it,j}V_{it}|\alpha_i]$, $g_{t,j} = E[f_{it,j}V_{it}|\gamma_t]$, and $e_{it,j} = f_{it,j}V_{it} - a_{i,j} - g_{t,j}$, for $j = 1, \dots, p$.

To show the regularization event holds with probability approaching one, we bound the probability of the following event for each $j = 1, \dots, p$:

$$\begin{aligned} & P\left(\frac{1}{NT} \left| \sum_{i=1}^N \sum_{t=1}^T \omega_j^{-1/2} f_{it,j} V_{it} \right| > \frac{\lambda}{2c_1 NT}\right) = P\left(\omega_j^{-1/2} \left| \frac{1}{N} \sum_{i=1}^N a_{i,j} + \frac{1}{T} \sum_{t=1}^T g_{t,j} + \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T e_{it,j} \right| > \frac{\lambda}{2c_1 NT}\right) \\ & \leq P\left(\left| \frac{1}{N} \sum_{i=1}^N \omega_{a,j}^{-1/2} a_{i,j} \right| + \left| \frac{1}{T} \sum_{t=1}^T \omega_{g,j}^{-1/2} g_{t,j} \right| + \left| \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \omega_j^{-1/2} e_{it,j} \right| > \frac{\lambda}{2c_1 NT}\right) \\ & \leq P\left(\left| \frac{(N \wedge T)^{1/2}}{N} \sum_{i=1}^N \omega_{a,j}^{-1/2} a_{i,j} \right| > \frac{(N \wedge T)^{1/2} \lambda}{6c_1 NT}\right) + P\left(\left| \frac{(N \wedge T)^{1/2}}{T} \sum_{t=1}^T \omega_{g,j}^{-1/2} g_{t,j} \right| > \frac{(N \wedge T)^{1/2} \lambda}{6c_1 NT}\right) \\ & \quad + P\left(\left| \frac{(N \wedge T)^{1/2}}{NT} \sum_{i=1}^N \sum_{t=1}^T \omega_j^{-1/2} e_{it,j} \right| > \frac{(N \wedge T)^{1/2} \lambda}{6c_1 NT}\right) := p_{1,j}(\lambda) + p_{2,j}(\lambda) + p_{3,j}(\lambda) \end{aligned}$$

where $\omega_{a,j} := \frac{N \wedge T}{N^2} \sum_{i=1}^N a_{i,j}^2$ and $\omega_{g,j} := \frac{N \wedge T}{T^2} \sum_{b=1}^B \left(\sum_{t \in H_b} g_{t,j} \right)^2$. The equality follows from the Hajek projection and it is definitional. The first inequality follows from the triangle inequality and the fact that $\omega_j^{1/2} = (\omega_{a,j} + \omega_{g,j})^{1/2} \geq \max\{\omega_{a,j}^{1/2}, \omega_{g,j}^{1/2}\}$. The third inequality follows from a union-bound inequality. Then, by the union-bound inequality again, we have

$$P\left(\max_{j=1, \dots, p} \left| \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \omega_j^{-1/2} f_{it,j} V_{it} \right| > \frac{\lambda}{2c_1 NT}\right) \leq \sum_{j=1}^p [p_{1,j}(\lambda) + p_{2,j}(\lambda) + p_{3,j}(\lambda)]$$

To bound $p_{1,j}(\lambda)$, we will apply a moderate deviation theorem for self-normalized sums of independent random variables. For $j = 1, \dots, p$, define

$$\Xi_{a,j} = \frac{[E(a_{i,j}^2)]^{1/2}}{[E(a_{i,j}^3)]^{1/3}}.$$

Let $l_{a,NT}$ be some positive increasing sequence. Without loss of generality, we assume $N \wedge T = N$ from now on. By Theorem 7.4 of Peña et al. (2009) with $\delta = 1$, we have for any $x \in [0, N^{1/6} \Xi_{a,j} / l_{a,NT}]$ that

$$P\left(\left| \frac{1}{N^{1/2}} \sum_{i=1}^N \omega_{a,j}^{-1/2} a_{i,j} \right| > x\right) \leq 2(1 - \Phi(x)) \left[1 + O(1) \left(\frac{1}{l_{a,NT}} \right)^3 \right]$$

Then, setting $\lambda = 6c_1 \sqrt{NT^2} \Phi^{-1} \left(1 - \frac{\gamma}{2p} \right)$ gives

$$p_{1,j}(\lambda) \leq 2(1 - \Phi(\Phi^{-1}(1 - \gamma/2p))) \leq \frac{\gamma}{p} [1 + O(1)(1/l_{a,NT})^3]$$

given that $\Phi^{-1} \left(1 - \frac{\gamma}{2p} \right) \in [0, N^{1/6} \Xi_{a,j}/l_{a,NT}]$ for all $j = 1, \dots, p$. And so we have

$$\sum_{j=1}^p p_{1,j}(\lambda) \leq \gamma [1 + O(1)(1/l_{a,NT})^3],$$

To show the right-hand-side converges to 0 as $\gamma \rightarrow 0$ and $(N, T) \rightarrow \infty$, there should exist an increasing sequence $l_{a,NT}$ such that $\Phi^{-1} \left(1 - \frac{\gamma}{2p} \right) \in [0, N^{1/6} \min_j \{\Xi_{a,j}\}/l_{a,NT}]$. Under Assumption REG and $N/T \rightarrow c$, we have $\log(p/\gamma) = o(N^{1/3})$ as $(N, T) \rightarrow \infty$. It follows that

$$N^{1/6} \min_j \{\Xi_{a,j}\}/l_{a,NT} = O(N^{1/6}/l_{a,NT})$$

$$\Phi^{-1} \left(1 - \frac{\gamma}{2p} \right) \lesssim \sqrt{\log(p/\gamma)} = o(N^{1/6})$$

Therefore, such positive sequence $l_{a,NT} \rightarrow \infty$ indeed exists and so we conclude $\sum_{j=1}^p p_{1,j}(\lambda) \rightarrow 0$ as $\gamma \rightarrow 0$ and $(N, T) \rightarrow \infty$.

To bound $p_{2,j}(\lambda)$, we utilize a moderate deviation theorem for self-normalized sums of weakly dependent random variables. Observe that $g_{t,j} = E[f_{it,j} V_{it} | \gamma_t]$ is beta-mixing with coefficient $\beta_g(q)$ satisfying

$$\beta_g(q) \leq \beta_\gamma(q) \leq c_\kappa \exp(-\kappa q) \quad \forall q \in \mathbb{Z}^+$$

Then, by Theorem 3.2 of Gao et al. (2022) with $\tau = 1$ and $\alpha = \frac{1}{1+2\tau}$, we have

$$\mathbb{P} \left(\left| \frac{\sqrt{c}}{T^{1/2}} \sum_{t=1}^T \omega_{g,j}^{-1/2} g_{t,j} \right| > x \right) \leq 2(1 - \Phi(x)) \left[1 + O(1) \left(\frac{1}{l_{g,NT}} \right)^2 \right]$$

uniformly for $x \in (0, d_0(\log T)^{-1/2} T^{1/12}/l_{g,NT})$ where d_0 is some positive constant and $l_{g,NT}$ is some positive increasing sequence. Then setting $\lambda = 6c_1 \sqrt{NT^2} \Phi^{-1}(1 - \frac{\gamma}{2p})$ gives, for all $j = 1, \dots, p$,

$$p_{2,j}(\lambda) \leq \frac{\gamma}{p} \left[1 + O(1) \left(\frac{1}{l_{g,NT}} \right)^2 \right]$$

given that $\Phi^{-1}(1 - \frac{\gamma}{2p}) \in (0, d_0(\log T)^{-1/2}T^{1/12}/l_{g,NT})$. And so we have

$$\sum_{j=1}^p p_{2,j}(\lambda) \leq \gamma \left[1 + O(1) \left(\frac{1}{l_{g,NT}} \right)^2 \right],$$

To show the right-hand-side converge to 0 as $\gamma \rightarrow 0$ and $(N, T) \rightarrow \infty$, there should exists an increasing sequence $l_{g,NT}$ such that $\Phi^{-1}(1 - \frac{\gamma}{2p}) \in (0, d_0(\log T)^{-1/2}T^{1/12}/l_{g,NT})$. Under Assumption REG, we have $\log(p/\gamma) = o(T^{1/6}/\log T)$ and so

$$\begin{aligned} d_0(\log T)^{-1/2}T^{1/12}/l_{g,NT} &= O(T^{1/12}/(\log T)^{1/2}/l_{g,NT}) \\ \Phi^{-1}\left(1 - \frac{\gamma}{2p}\right) &\simeq \sqrt{\log(p/\gamma)} = o(T^{1/12}/(\log T)^{1/2}). \end{aligned}$$

Therefore, such positive sequence $l_{g,NT} \rightarrow \infty$ indeed exists and so we conclude $\sum_{j=1}^p p_{2,j}(\lambda) \rightarrow 0$ as $\gamma \rightarrow 0$ and $(N, T) \rightarrow \infty$.

Consider $p_{3,j}(\lambda)$. Define $\bar{e}_{i,j} := \frac{1}{T} \sum_{t=1}^T e_{it,j}$. Observe that $E[\bar{e}_{i,j}] = 0$ by iterated expectation and conditional on $\{\gamma_t\}_{t=1}^T$, $\bar{e}_{i,j}$ are independent over i . By Assumption REG(iii) and Holder's inequality, we have $E|f_{it,j}V_{it}|^{4(s+\delta)} < \infty$ for some $s > 1$, $\delta > 0$. Given that $e_{it,j} = f_{it,j}V_{it} - a_{i,j} - g_{t,j}$ and $E|a_{i,j}|^{4(s+\delta)} < \infty$, $E|g_{t,j}|^{4(s+\delta)} < \infty$ due to Jansen's inequality and iterated expectation, we have $E|e_{it,j}|^{4(s+\delta)} < \infty$ and so $E|\bar{e}_{i,j}|^{4(s+\delta)} < \infty$ due to Minkowski's inequality. Under Assumptions AHK and AR, it is shown in the Proof of Theorem 1 from Chen and Vogelsang (2024) that $\text{Var}(\bar{e}_{i,j}) = \|\Lambda_e \Lambda_e'\|/T$ and $\|\Lambda_e \Lambda_e'\| < \infty$. Furthermore, as is shown below, $\omega_j^{1/2}$ is bounded from below by some constant $a > 0$. Now, by the conditional version of Corollary 4 from Fuk and Nagaev (1971), there exists some constant a_1 and a_2 such that

$$\begin{aligned} P\left(\left|\sum_{i=1}^N \omega_j^{-1/2} \bar{e}_{i,j}\right| > \frac{\lambda}{6c_1 T} |\{\gamma_t\}_{t=1}^T\right) &\leq P\left(\left|\sum_{i=1}^N \bar{e}_{i,j}\right| > \frac{a\lambda}{6c_1 T} |\{\gamma_t\}_{t=1}^T\right) \\ &\leq a_1(\lambda/T)^{-4} \sum_{i=1}^N E(|\bar{e}_{i,j}|^4 | \{\gamma_t\}_{t=1}^T) + \exp\left(-\frac{a_2(\lambda/T)^2}{\sum_{i=1}^N \text{Var}(\bar{e}_{i,j} | \{\gamma_t\}_{t=1}^T)}\right) \end{aligned}$$

Note that $F(z) = \exp(-1/z)$ is not globally concave but it is concave for $x > 1/2$ and is bounded by x/e^2 for $x \in (0, 1/2)$. Denote $z = \frac{(T/\lambda)^2}{a_2} \sum_{i=1}^N \text{Var}(\bar{e}_{i,j} | \{\gamma_t\}_{t=1}^T)$. Then, we have

$$\exp\left(-\frac{a_2(\lambda/T)^2}{\sum_{i=1}^N \text{Var}(\bar{e}_{i,j} | \{\gamma_t\}_{t=1}^T)}\right) \leq z/e^2 1\{z \in (0, 1)\} + \exp(-1/z) 1\{z > 1/2\}.$$

By Fubini theorem, Jensen's inequality, and the bounded moments, we have

$$\begin{aligned}
p_{3,j}(\lambda) &= \mathbb{P} \left(\left| \sum_{i=1}^N \omega_j^{-1/2} \bar{e}_{i,j} \right| > \frac{\lambda}{6c_1 T} \right) \\
&\leq a_1 (\lambda/T)^{-4} \sum_{i=1}^N E(|\bar{e}_{i,j}|^4) + \frac{(T/\lambda)^2}{a_2} \sum_{i=1}^N \text{Var}(\bar{e}_{i,j})/e^2 + \exp \left(-\frac{a_2 (\lambda/T)^2}{\sum_{i=1}^N \text{Var}(\bar{e}_{i,j})} \right) \\
&= O((\lambda/T)^{-4} N) + O \left(\frac{TN}{\lambda^2} \right) + \exp \left(-\frac{a_2 (\lambda/T)^2}{N/T \Lambda_e \Lambda'_e} \right).
\end{aligned}$$

Therefore, we have $\sum_{j=1}^p p_{3,j}(\lambda) = O(p(\lambda/T)^{-4} N) + O \left(\frac{pTN}{\lambda^2} \right) + p \exp \left(-\frac{a_2 (\lambda/T)^2}{N/T \Lambda_e \Lambda'_e} \right)$. Given that $N/T \rightarrow c$ where $0 < c < \infty$, by taking $\lambda_e = \frac{p^{1/4} T N^{1/4}}{\varepsilon^{1/4}} \vee \frac{\sqrt{pNT}}{\varepsilon^{1/2}} \vee \frac{\sqrt{NT \log(p/\gamma)}}{\sqrt{a_2/\Lambda_e \Lambda'_e}}$ for some $\varepsilon = o(1)$, $\sum_{j=1}^p p_{3,j}(\lambda_e) = o(1)$. Under REG(ii), $\log(p/\gamma) = o(T^{1/6}/\log T)$ and $p = o(T^{7/6} \log T)$, then $\lambda_e = O(\lambda)$ where $\lambda = 6c_1 \sqrt{NT^2} \Phi^{-1}(1 - \frac{\gamma}{2p})$. Therefore, we have shown $\sum_{j=1}^p p_{3,j}(\lambda) \rightarrow 0$ for $\lambda = 6c_1 \sqrt{NT^2} \Phi^{-1}(1 - \frac{\gamma}{2p})$.

Put together, we have shown, for all (k, l) ,

$$\mathbb{P} \left(\max_{j=1, \dots, p} \left| \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \omega_j^{-1/2} f_{it,j} V_{it} \right| \leq \frac{\lambda}{2c_1 NT} \right) \rightarrow 1. \quad (7.1)$$

Secondly, we will apply Lemma 6 of Belloni et al. (2012) to obtain the finite sample bounds on

$$\begin{aligned}
\left\| f_{it} (\hat{\zeta} - \zeta_0) \right\|_{NT,2} &= \left(\frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T (f_{it} \hat{\zeta} - f_{it} \zeta_0)^2 \right)^{1/2}, \\
\left| \omega^{1/2} (\hat{\zeta} - \zeta_0) \right|_1 &= \left| \sum_{j=1}^p \omega_j^{1/2} (\hat{\zeta}_j - \zeta_{0,j}) \right|.
\end{aligned}$$

Let δ be some generic vector of nuisance parameters and let J_p^1 be a subset of an index set $J_p = 1, \dots, p$ and $J_p^0 = J_p \setminus J_p^1$. Let δ^1 be a copy of δ with its j -th element replaced by 0 for all $j \in J_p^0$ and similarly let δ^0 be a copy of δ with its j -th element replaced by 0 for all $j \in J_p^1$. Define the restricted eigenvalues and Gram matrix as follows:

$$\begin{aligned}
K_C(M_f) &= \min_{\delta: \|\delta^0\|_1 \leq C \|\delta^1\|_1, \|\delta\| \neq 0, |J_p^1| \leq s} \frac{\sqrt{s \delta' M_f \delta}}{\|\delta^1\|_1}, \\
M_f &= \frac{1}{NT} \sum_{i \in I_k, t \in T_l} f_{it} f'_{it}.
\end{aligned}$$

Define the weighted restricted eigenvalues as follows:

$$K_C^\omega(M_f) = \min_{\delta: \|\omega^{1/2}\delta^0\|_1 \leq C\|\omega^{1/2}\delta^1\|_1, \|\delta\| \neq 0, |J_p^1| \leq s} \frac{\sqrt{s\delta' M_f \delta}}{\|\omega^{1/2}\delta^1\|_1}.$$

Let $a := \min_{j=1,\dots,p} \omega_j^{1/2}$, $b := \max_{j=1,\dots,p} \omega_j^{1/2}$. As is shown in Belloni et al. (2016),

$$K_C^\omega(M_f) \geq \frac{1}{b} K_{bC/a}(M_f). \quad (7.2)$$

By results in Chiang et al. (2024), we have, as $N, T \rightarrow \infty$ jointly,

$$\omega_j \xrightarrow{p} \frac{N \wedge T}{N} \lambda_{a,j}^2 + \frac{N \wedge T}{T} \lambda_{g,j}^2 \quad \text{for each } j = 1, \dots, p.$$

By Theorem 2 of Chiang et al. (2024), we have $|\lambda_{a,j}^2| < \infty$ and $|\lambda_{g,j}^2| < \infty$. By the non-degeneracy assumption, we have either $\lambda_{a,j}^2 > 0$ or $\lambda_{g,j}^2 > 0$. Therefore, we have ω_j bounded below by zero and bounded above for each $j = 1, \dots, p$ with probability approaching one as $N, T \rightarrow \infty$.

Under Assumption (ASM), the condition 2.9, and 7.1, Lemma 6 of Belloni et al. (2012) implies that

$$\begin{aligned} \left\| f_{it}(\hat{\xi} - \xi_0) \right\|_{NT,2} &\leq \left(u + \frac{1}{c_1} \right) \frac{\sqrt{s}\lambda}{NT K_{c_0}^\omega(M_f)} + 2 \|r\|_{NT,2}, \\ &= O_P \left(\frac{1}{K_{c_0}^\omega(M_f)} \sqrt{\frac{s \log(p/\gamma)}{N \wedge T}} + \sqrt{\frac{s}{N \wedge T}} \right), \\ \left\| \omega^{1/2}(\hat{\xi} - \xi_0) \right\|_1 &\leq \frac{3c_0 \sqrt{s}}{K_{2c_0}^\omega(M_f)} \left[\left(u + \frac{1}{c_1} \right) \frac{\sqrt{s}\lambda}{NT K_{c_0}^\omega(M_f)} + 2 \|r\|_{NT,2} \right] + 3c_0 \frac{NT}{\lambda} \|r\|_{NT,2}^2, \\ &= O_P \left(\frac{s}{K_{2c_0}^\omega(M_f) K_{c_0}^\omega(M_f)} \sqrt{\frac{\log(p/\gamma)}{N \wedge T}} + \sqrt{\frac{s}{N \wedge T}} + \frac{s/\sqrt{N \wedge T}}{\log(p/\gamma)} \right) \end{aligned}$$

where $c_0 := \frac{uc+1}{lc-1} > 1$. By 7.2, we have $1/K_{c_0}^\omega(M_f) \leq b/K_{\bar{C}}(M_f)$ where $\bar{C} := bc_0/a$. By arguments given in Bickel et al. (2009), Assumption SE implies that $1/K_C(M_f) = O_P(1)$ for any $C > 0$. Therefore,

$$\begin{aligned} \left\| f_{it}(\hat{\xi} - \xi_0) \right\|_{NT,2} &= O_P \left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}} \right), \\ \left| \omega^{1/2}(\hat{\xi} - \xi_0) \right|_1 &= O_P \left(s \sqrt{\frac{\log(p/\gamma)}{N \wedge T}} \right), \end{aligned}$$

Then, applying the results above gives

$$\|\hat{\xi} - \xi_0\|_1 \leq \|\omega^{-1/2}\|_\infty \left| \omega^{1/2} (\hat{\xi} - \xi_0) \right|_1 = O_P \left(s \sqrt{\frac{\log(p/\gamma)}{N \wedge T}} \right) = O_P \left(s \sqrt{\frac{\log(p \vee NT)}{N \wedge T}} \right)$$

where the first inequality follows from the Holder's.

The l_2 rate of convergence will be derived after the sparsity bounds. We now switch the focus to the Post-LASSO. The proof follows closely Steps 5-8 of Theorem 1 in Belloni et al. (2016). Corresponding to $\hat{\Gamma}$ defined above Theorem 2.1, here we define Γ_0 as the support of ξ_0 . Define $\hat{m} = \|\hat{\Gamma} \setminus \Gamma_0\|_0$. Define \mathcal{P}_Γ as the projection matrix such that it projects an $NT \times 1$ vector onto the linear span of $NT \times 1$ vector f_j with $j \in \Gamma$. We want to show, first, under Assumptions AHK, ASM, AR, REG,

$$\begin{aligned} \|f(X_{it}) - f_{it}\hat{\xi}_{PL}\|_{NT,2} &= O_P \left(\sqrt{\frac{s \log(p/\gamma)}{(N \wedge T)\phi_{\min}(s)(M_f)}} + \sqrt{\frac{\hat{m} \log(p/\gamma)}{(N \wedge T)\phi_{\min}(\hat{m})(M_f)}} \right) \\ &\quad + O_P \left(\|f(X_{it}) - (\mathcal{P}_{\hat{\Gamma}} f)_{it}\|_{NT,2} \right), \end{aligned} \quad (7.3)$$

$$\|f_{it}(\hat{\xi}_{PL} - \xi_0)\|_{NT,2} \leq \|f_{it}(X_{it}) - f_{it}\hat{\xi}_{PL}\|_{NT,2} + \|r_{it}\|_{NT,2}, \quad (7.4)$$

$$\|\omega^{1/2}(\hat{\xi}_{PL} - \xi_0)\|_1 \leq \frac{b\sqrt{\hat{m} + s}}{\sqrt{\phi_{\min}(\hat{m} + s)(M_f)}} \times \|f_{it}(\hat{\xi}_{PL} - \xi_0)\|_{NT,2} \quad (7.5)$$

Let $S_j := 2\mathbb{E}_{NT}[\omega^{-1/2}f_{it,j}V_{it}]$. Furthermore, under $c_1 \max_{1 \leq j \leq p} |S_j| \leq \frac{\lambda}{NT}$ and $u \geq 1 \geq l \geq 1/c_1$, we want to show

$$\|f(X_{it}) - \mathcal{P}_{\hat{\Gamma}} f(X_{it})\|_{NT,2} \leq \left(u + \frac{1}{c_1} \right) \frac{\lambda \sqrt{s}}{NT K_{c_0}^\omega(M_f)} + 3\|r_{it}\|_{NT,2}. \quad (7.6)$$

First, note that

$$f(X_{it}) - f_{it}\hat{\xi}_{PL} = f(X_{it}) - (\mathcal{P}_{\hat{\Gamma}} Y)_{it} = ((I_{NT} - \mathcal{P}_{\hat{\Gamma}})f(X) - \mathcal{P}_{\hat{\Gamma}} V)_{it} = ((I_{NT} - \mathcal{P}_{\hat{\Gamma}})f - (\mathcal{P}_{\hat{\Gamma} \setminus \Gamma_0} + \mathcal{P}_{\Gamma_0})V)_{it},$$

where the last inequality follows from the property of the linear projection. Then, by Minkowski inequality, we have

$$\|f(X_{it}) - f_{it}\hat{\xi}_{PL}\|_{NT,2} \leq \left\| (I_{NT} - \mathcal{P}_{\hat{\Gamma}})f \right\|_{NT,2} + \left\| (\mathcal{P}_{\Gamma_0} V)_{it} \right\|_{NT,2} + \left\| (\mathcal{P}_{\hat{\Gamma} \setminus \Gamma_0} V)_{it} \right\|_{NT,2}. \quad (7.7)$$

We will proceed by bounding the last two terms above. First, consider the last term. By Hölder's inequality

and the property of spectral norm, we have

$$\begin{aligned} \left\| \left(\mathcal{P}_{\hat{\Gamma} \setminus \Gamma_0} V \right)_{it} \right\|_{NT,2} &= \frac{1}{\sqrt{NT}} \left\| \mathcal{P}_{\hat{\Gamma} \setminus \Gamma_0} V \right\|_2 \leq \frac{1}{\sqrt{NT}} \left\| f_{\hat{\Gamma} \setminus \Gamma_0} (f'_{\hat{\Gamma} \setminus \Gamma_0} f_{\hat{\Gamma} \setminus \Gamma_0})^{-1} \right\|_{\infty} \left\| f'_{\hat{\Gamma} \setminus \Gamma_0} V \right\|_2 \\ &\leq \frac{1}{\sqrt{NT}} \sqrt{\frac{1}{NT \phi_{\min}(\hat{m})(M_f)}} \left(\sum_{j \in \hat{\Gamma} \setminus \Gamma_0} \left(\sum_{i=1}^N \sum_{t=1}^T f_{it,j} V_{it} \right)^2 \right)^{1/2} \leq \frac{1}{NT} \sqrt{\frac{\hat{m}}{\phi_{\min}(\hat{m})(M_f)}} \max_{j=1,\dots,p} \left| \sum_{i=1}^N \sum_{t=1}^T f_{it,j} V_{it} \right|. \end{aligned}$$

We have shown previously that $b = \max_{j=1,\dots,p} \omega_j^{1/2} < \infty$, so

$$\frac{1}{NT} \max_{j=1,\dots,p} \left| \sum_{i=1}^N \sum_{t=1}^T f_{it,j} V_{it} \right| \leq b/2 \max_{j=1,\dots,p} |S_j| = O_P(\lambda/NT) = O_P \left(\frac{\Phi^{-1} \left(1 - \frac{\gamma}{2p} \right)}{\sqrt{N \wedge T}} \right) = O_P \left(\sqrt{\frac{\log(p/\gamma)}{N \wedge T}} \right).$$

Next, consider the middle term.

$$\begin{aligned} \left\| \left(\mathcal{P}_{\Gamma_0} V \right)_{it} \right\|_{NT,2} &= \frac{1}{\sqrt{NT}} \left\| \mathcal{P}_{\Gamma_0} V \right\|_2 \leq \frac{1}{\sqrt{NT}} \left\| f_{\Gamma_0} (f'_{\Gamma_0} f_{\Gamma_0})^{-1} \right\|_{\infty} \left\| f'_{\Gamma_0} V \right\|_2 \\ &\leq \frac{1}{\sqrt{NT}} \sqrt{\frac{1}{NT \phi_{\min}(s)(M_f)}} \left(\sum_{j \in \Gamma_0} \left(\sum_{i=1}^N \sum_{t=1}^T f_{it,j} V_{it} \right)^2 \right)^{1/2} \leq \frac{1}{NT} \sqrt{\frac{s}{\phi_{\min}(s)(M_f)}} \max_{j=1,\dots,p} \left| \sum_{i=1}^N \sum_{t=1}^T f_{it,j} V_{it} \right| \\ &= O_P \left(\sqrt{\frac{s}{\phi_{\min}(s)(M_f)} \frac{\log(p/\gamma)}{N \wedge T}} \right). \end{aligned}$$

Combining the bounds for the last two terms and 7.7, we obtain the inequality 7.3. The inequality 7.4 follows directly from the triangle inequality. The inequalities 7.5 and 7.5 follow from Lemma 7 of Belloni et al. (2012) since there are finite sample bounds, not affected by the panel data dependence.

Next, to obtain the sparsity bound for the two-way cluster LASSO estimator, we first apply Lemma 8 of Belloni et al. (2012) to obtain that

$$\hat{m} \leq \phi_{\max}(\hat{m})(M_f) a^{-2} \left(\frac{2c_0 \sqrt{s}}{K_{c_0}^{\omega}(M_f)} + \frac{6c_0 NT \|r_{it}\|_{NT,2}}{\lambda} \right)^2.$$

where $a > 0$ has been shown previously.

Let $\mathcal{M} = \left\{ m \in \mathbb{N} : m > 2\phi_{\max}(m)(M_f) a^{-2} \left(\frac{2c_0 \sqrt{s}}{K_{c_0}^{\omega}(M_f)} + \frac{6c_0 NT \|r_{it}\|_{NT,2}}{\lambda} \right)^2 \right\}$. Then, by Lemma 10 of Belloni et al. (2012), we have

$$\hat{m} \leq \min_{m \in \mathcal{M}} \phi_{\max}(m \wedge NT)(M_f) a^{-2} \left(\frac{2c_0 \sqrt{s}}{K_{c_0}^{\omega}(M_f)} + \frac{6c_0 NT \|r_{it}\|_{NT,2}}{\lambda} \right)^2. \quad (7.8)$$

Note that $\frac{6c_0NT\|r_{it}\|_{NT,2}}{\lambda\sqrt{s}} = O_P(1/\log(p \wedge NT)) \xrightarrow{P} 0$. Recall that $1/K_{c_0}^\omega(M_f) \leq b/K_{\bar{C}}(M_f) < \infty$. Let $\mu := \min_m \left\{ \sqrt{\phi_{\max}(m)(M_f)/\phi_{\min}(m)(M_f)} : m > 18\bar{C}^2 s \phi_{\max}(m)(M_f)/K_{\bar{C}}^2(M_f) \right\}$, and let \bar{m} be the integer associated with μ . By the definition of \mathcal{M} , it implies that $\bar{m} \in \mathcal{M}$ with probability approaching one, which implies $\bar{m} > \hat{m}$ due to 7.8. By Lemma 9 (the sub-linearity of sparse eigenvalues) from Belloni et al. (2012) and 7.8, we have

$$\hat{m} \lesssim_P s\mu^2 \phi_{\min}(\bar{m} + s)/K_{\bar{C}}^2 \lesssim s\mu^2 \phi_{\min}(\hat{m} + s)/K_{\bar{C}}^2.$$

Recall that $c_1 \max_{1 \leq j \leq p} |S_j| \leq \frac{\lambda}{NT}$ with probability approaching one, so we can combine the results above with 7.3 and 7.6 to obtain

$$\|f(X_{it}) - f_{it}\hat{\xi}_{PL}\|_{NT,2} = O_P \left(\sqrt{\frac{s\mu^2 \log(p/\gamma)}{(N \wedge T)K_{\bar{C}}^2}} + \|r_{it}\|_{NT,2} + \frac{\lambda\sqrt{s}}{NTK_{c_0}^\omega(M_f)} \right).$$

Recall that $b < \infty$ and Condition SE imply $1/K_{c_0}^\omega(M_f) \leq 1/K_{\bar{C}}(M_f) < \infty$. Then, Condition SE, Condition ASM and the choice of λ together imply

$$\|f(X_{it}) - f_{it}\hat{\xi}_{PL}\|_{NT,2} = O_P \left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}} \right).$$

For the l_1 convergence rate, note that $\|\hat{\xi}_{PL} - \zeta_0\|_0 \leq \hat{m} + s$. Then, applying Cauchy-Schwarz inequality to $\|\hat{\xi}_{PL} - \zeta_0\|_1 = \sum_{j=1}^p |\hat{\xi}_{PL} - \zeta_0| = \sum_{j \in \{\hat{\Gamma} \cup \Gamma_0\}} |\hat{\xi}_{PL} - \zeta_0|$ gives

$$\|\hat{\xi}_{PL} - \zeta_0\|_1 \leq \sqrt{\hat{m} + s} \|\hat{\xi}_{PL} - \zeta_0\|_2$$

To derive the convergence rates in l_2 -norm of the Post-LASSO estimator (the l_2 rate for the LASSO estimator is obtained similarly), we will utilize the sparse eigenvalue condition and the prediction norm. If $\hat{\xi}_{PL} - \zeta_0 = 0$, then the conclusion holds trivially. Otherwise, define $b = (\hat{\xi}_{PL} - \zeta_0) / \|\hat{\xi}_{PL} - \zeta_0\|_2^{-1}$. Then, we have $\|b\|_2 = 1$ and so $b \in \Delta(\hat{m} + s) = \{\delta : \|\delta\|_0 = \hat{m} + s, \|\delta\|_2 = 1\}$. By Assumption SE, we have

$$0 < \kappa_1 \leq \phi_{\min}(\hat{m} + s)(M_f) \leq \frac{(b' M_f b)^{1/2}}{\|b\|_2} = \frac{\left\| f_{it} (\hat{\xi}_{PL} - \zeta_0) \right\|_{NT,2}}{\|\hat{\xi}_{PL} - \zeta_0\|_2},$$

Therefore, using the bound on the prediction norm above, we conclude that

$$\|\hat{\xi}_{PL} - \zeta_0\|_2 \leq \frac{\left\| f_{it} (\hat{\xi}_{PL} - \zeta_0) \right\|_{NT,2}}{\kappa_1} = O_P \left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}} \right).$$

It implies that $\|\hat{\zeta}_{PL} - \zeta_0\|_1 = \sqrt{\hat{m}} + sO_P\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right) = O_P\left(\sqrt{\frac{s^2 \log(p/\gamma)}{N \wedge T}}\right)$. \square

Appendix B

The following lemma, quoted from Semenova et al. (2023a)(Lemma A.3), is a result follows from the weak form of Strassen's coupling Strassen (1965) and the strong form of Strassen's coupling via Lemma 2.11 of Dudley and Philipp (1983):

Lemma B.1 *Let (X, Y) be random element taking values in Polish space $S = (S_1 \times S_2)$ with laws P_X and P_Y , respectively. Then, we can construct (\tilde{X}, \tilde{Y}) taking values in (S_1, S_2) such that (i) they are independent of each other; (ii) their laws $\mathcal{L}(\tilde{X}) = P_X$ and $\mathcal{L}(\tilde{Y}) = P_Y$; (iii)*

$$\mathbb{P}\{(X, Y) \neq (\tilde{X}, \tilde{Y})\} = \frac{1}{2} \|P_{X,Y} - P_X \times P_Y\|_{TV}$$

The proof is provided in Semenova et al. (2023b). To apply the independence coupling result for cross-fitting in the panel data, we need to introduce another lemma:

Lemma B.2 *Let X_1, \dots, X_q and Y be random elements taking values in Polish space $S = (S_1 \times \dots \times S_m \times S_y)$.*

$$\beta((X_1, \dots, X_m), Y) \leq \sum_{i=1}^q \beta(X_i, Y).$$

Proof of Lemma B.2. By Lemma B.1, we have

$$\begin{aligned} \beta((X_1, \dots, X_m), Y) &= \frac{1}{2} \left\| P_{(X_1, \dots, X_q), Y} - P_{(X_1, \dots, X_m)} \times P_Y \right\|_{TV} \\ &= \mathbb{P}((X_1, \dots, X_m, Y) \neq (\tilde{X}_1, \dots, \tilde{X}_m, \tilde{Y})) \\ &\leq \sum_{i=1}^m \mathbb{P}((X_i, Y) \neq (\tilde{X}_i, \tilde{Y})) \\ &= \sum_{i=1}^m \beta(X_i, Y), \end{aligned}$$

where the inequality follows from the union bound. \square

Now we can prove Lemma 3.1 from the main body of the paper:

Proof of Lemma 3.1. By Lemma B.1, for each (k, l) we have

$$\begin{aligned}
& \mathbb{P}\{(W(k, l), W(-k, -l)) \neq (\tilde{W}(k, l), \tilde{W}(-k, -l))\} \\
&= \beta(W(k, l), W(-k, -l)) \\
&= \beta\left(\{W_{it}\}_{i \in I_k, t \in S_l}, \bigcup_{k' \neq k, l' \neq l, l \pm 1} \{W_{it}\}_{i \in I_{k'}, t \in S_{l'}}\right) \\
&\leq \sum_{i \in I_k} \beta\left(\{W_{it}\}_{t \in S_l}, \bigcup_{k' \neq k, l' \neq l, l \pm 1} \{W_{it}\}_{i \in I_{k'}, t \in S_{l'}}\right) \\
&\leq \sum_{k' \neq k, l' \neq l, l \pm 1} \sum_{j \in I_{k'}} \sum_{i \in I_k} \beta\left(\{W_{it}\}_{t \in S_l}, \{W_{jt}\}_{t \in S_{l'}}\right)
\end{aligned}$$

where the last two inequalities follow from Lemma B.2. Note that for $s, m \geq 1$, we have

$$\begin{aligned}
\beta(\{W_{it}\}_{t \leq s}, \{W_{jt}\}_{t \geq s+m}) &= \left\| P_{\{W_{it}\}_{t \leq s}, \{W_{jt}\}_{t \geq s+m}} - P_{\{W_{it}\}_{t \leq s}} \times P_{\{W_{jt}\}_{t \geq s+m}} \right\|_{TV} \\
&\leq \sup_{A \in \sigma(\{W_{jt}\}_{t \geq s+m})} \mathbb{E}_P |\mathbb{P}(A | \sigma(\{W_{it}\}_{t \leq s})) - \mathbb{P}(A)| \\
&= \sup_{A \in \sigma(\{W_{jt}\}_{t \geq s+m})} \mathbb{E}_P |\mathbb{P}(\mathbb{P}(A | \sigma(\alpha_i, \{\gamma_t\}_{t \leq s}, \{\varepsilon_{it}\}_{t \leq s})) | \sigma(\{W_{it}\}_{t \leq s})) - \mathbb{P}(A)| \\
&= \sup_{A \in \sigma(\{W_{jt}\}_{t \geq s+m})} \mathbb{E}_P |\mathbb{P}(A | \sigma(\{\gamma_t\}_{t \leq s})) - \mathbb{P}(A)| \\
&= \sup_{A \in \sigma(\{\gamma_t\}_{t \geq s+m})} \mathbb{E}_P |\mathbb{P}(A | \sigma(\{\gamma_t\}_{t \leq s})) - \mathbb{P}(A)| \leq c_\kappa \exp(-\kappa m),
\end{aligned}$$

where the last inequality follows from Assumption 2. Therefore,

$$\mathbb{P}\{(W(k, l), W(-k, -l)) \neq (\tilde{W}(k, l), \tilde{W}(-k, -l))\} \leq K L N^2 c_\kappa \exp(-\kappa T_l),$$

which in turn gives

$$\mathbb{P}\{(W(k, l), W(-k, -l)) \neq (\tilde{W}(k, l), \tilde{W}(-k, -l)), \text{ for some } (k, l)\} \leq K^2 L^2 N^2 c_\kappa \exp(-\kappa T_l),$$

where $T_l = T/L$. Given that $\log(N)/T = o(1)$ and (K, L) are finite, it follows that

$$\mathbb{P}\{(W(k, l), W(-k, -l)) \neq (\tilde{W}(k, l), \tilde{W}(-k, -l)), \text{ for some } (k, l)\} = o(1)$$

□

Appendix C

For proving Theorem 3.1, we need another lemma, which is quoted from Chernozhukov et al. (2018a) and restated as follows:

Lemma C.1 (Conditional convergence implies unconditional) *Let $\{X_m\}$ and $\{Y_m\}$ be sequences of random vectors. (i) If, for $\epsilon_m \rightarrow 0$, $P(\|X_m\| > \epsilon_m | Y_m) \xrightarrow{p} 0$, then $P(\|X_m\| > \epsilon_m) \rightarrow 0$. In particular, this occurs if $E_P[\|X_m\|^q / \epsilon_m^q] \xrightarrow{p} 0$ for some $q \geq 1$, by Markov inequality. (ii) Let $\{A_m\}$ be a sequence of positive constants. If $\|X_m\| = O_P(A_m)$ conditional on Y_m , namely, that for any $l_m \rightarrow \infty$, $P(\|X_m\| > l_m A_m | Y_m) \xrightarrow{p} 0$, then $\|X_m\| = O_P(A_m)$ unconditionally, namely, that for any $l_m \rightarrow \infty$, $P(\|X_m\| > l_m A_m) \rightarrow 0$.*

Proof of Theorem 3.1. By Assumption DML2(i), with probability $1 - \Delta_{NT}$, $\hat{\eta}_{kl} \in \mathcal{T}_{NT}$. So, $P(\hat{\eta}_{kl} \in \mathcal{T}_{NT}, \forall(k, l)) \geq 1 - KL\Delta_{NT} = 1 - o(1)$. Let's denote the event $P(\hat{\eta}_{kl} \in \mathcal{T}_\eta, \forall(k, l))$ as \mathcal{E}_η and the event $\{(W(k, l), W(-k, -l)) = (\tilde{W}(k, l), \tilde{W}(-k, -l)), \text{ for some } (k, l)\}$ as \mathcal{E}_{cp} . By Lemma 3.1, we have $P(\mathcal{E}_{cp}) = 1 - o(1)$. By union bound inequality, we have $P(\mathcal{E}_\eta^c \cup \mathcal{E}_{cp}^c) \leq P(\mathcal{E}_\eta^c) + P(\mathcal{E}_{cp}^c) = o(1)$. So, $P(\mathcal{E}_\eta \cap \mathcal{E}_{cp}) = 1 - P(\mathcal{E}_\eta^c \cup \mathcal{E}_{cp}^c) \geq 1 - o(1)$.

Let $\hat{\theta}$ be a solution from equation 3.1. Denote

$$\begin{aligned}\hat{A}_{kl} &= \mathbb{E}_{kl}[\psi^a(W_{it}, \hat{\eta}_{kl})], \quad \hat{A} = \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \hat{A}_{kl}, \quad A_0 = E_P[\psi^a(W_{it}; \eta_0)], \\ \hat{B}_{kl} &= \mathbb{E}_{kl}[\psi^b(W_{it}, \hat{\eta}_{kl})], \quad \hat{B} = \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \hat{B}_{kl}, \quad B_0 = E_P[\psi^b(W_{it}; \eta_0)], \\ \hat{\psi}(\theta) &= \hat{A}\theta + \hat{B}, \quad \tilde{\psi}(\theta, \eta) = \mathbb{E}_{NT}\psi(W_{it}; \theta, \eta).\end{aligned}$$

Claim C.1. On event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, $\|\hat{A} - A_0\| = O_P(N^{-1/2} + r_{NT})$.

By Claim 1 and Assumption 3(iii) that all singular values of A_0 are bounded below by zero, it follows that all singular values of \hat{A} are also bounded below from zero, on event \mathcal{E}_η . Then, by the linearity in Assumption 3(i), we can write

$$\hat{\theta} = -\hat{A}^{-1}\hat{B}, \quad \theta_0 = -A_0^{-1}B_0.$$

Then, we have

$$\begin{aligned}
\sqrt{N}(\hat{\theta} - \theta_0) &= \sqrt{N}(-\hat{A}^{-1}\hat{B} - \theta_0) = -\sqrt{N}\hat{A}^{-1}(\hat{B} + \hat{A}\theta_0) = -\sqrt{N}\hat{A}^{-1}\hat{\psi}(\theta_0) \\
&= \sqrt{N}\left(A_0 + \hat{A} - A_0\right)^{-1}\left(\bar{\psi}(\theta_0, \eta_0) + \hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\right) \\
&= \sqrt{N}A_0^{-1}\bar{\psi}(\theta_0, \eta_0) + \sqrt{N}A_0^{-1}\left(\hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\right) \\
&\quad + \sqrt{N}\left[\left(A_0 + \hat{A} - A_0\right)^{-1} - A_0^{-1}\right]\left(\bar{\psi}(\theta_0, \eta_0) + \hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\right)
\end{aligned}$$

Claim C.2. On event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, $\|\hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\| = O_P(r'_{NT}/\sqrt{N} + \lambda_{NT} + \lambda'_{NT})$.

By Claim C.2, we have

$$\begin{aligned}
\|\sqrt{N}A_0^{-1}\left(\hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\right)\| &= O_P(1)O_P(\sqrt{N}r'_{NT} + \sqrt{N}\lambda_{NT} + \sqrt{N}\lambda'_{NT}) \\
&= O_P(r'_{NT} + \sqrt{N}\lambda_{NT} + \sqrt{N}\lambda'_{NT}),
\end{aligned}$$

Claim C.3. $\sqrt{N}\bar{\psi}(\theta_0, \eta_0) \xrightarrow{d} N(0, \Omega)$ where $\Omega = \Lambda_a\Lambda'_a + c\Lambda_g\Lambda'_g$ and $\|\Omega\| < \infty$.

By Claims A.1, A.2, and A.3, we have

$$\begin{aligned}
&\left\|\sqrt{N}\left[\left(A_0 + \hat{A} - A_0\right)^{-1} - A_0^{-1}\right]\left(\bar{\psi}(\theta_0, \eta_0) + \hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\right)\right\| \\
&\leq \left\|\hat{A}^{-1}\right\|\left\|\hat{A} - A_0\right\|\left\|A_0^{-1}\right\|\left\|\sqrt{N}\left(\bar{\psi}(\theta_0, \eta_0) + \hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0)\right)\right\| \\
&= O_P(1)O_P(N^{-1/2} + r_{NT})O_P(1)\left(O_P(1) + O_P\left(r'_{NT} + \sqrt{N}\lambda_{NT} + \sqrt{N}\lambda'_{NT}\right)\right) \\
&= O_P(N^{-1/2} + r_{NT}).
\end{aligned}$$

Now, we can combine the results and obtain

$$\sqrt{N}(\hat{\theta} - \theta_0) = A_0^{-1}N(0, \Omega) + O_P\left(N^{-1/2} + r_{NT} + r'_{NT} + \sqrt{N}\lambda_{NT} + \sqrt{N}\lambda'_{NT}\right) = A_0^{-1}N(0, \Omega) + o_P(1).$$

Proof of Claim C.1. Fix any (k, l) , we have

$$\left\|\hat{A}_{kl} - A_0\right\| \leq \left\|\hat{A}_{kl} - E_P[\hat{A}_{kl}|W(-k, -l)]\right\| + \left\|E_P[\hat{A}_{kl}|W(-k, -l)] - A_0\right\| =: \|\Delta_{A,1}\| + \|\Delta_{A,2}\|.$$

On the event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, we have $\hat{\eta}_{kl} \in \mathcal{T}_{NT}$ and the independence between $W(-k, -l)$ and $W(k, l)$. So, due to Assumption DML2, we have $\|\Delta_{A,2}\| \leq r_{NT}$. By iterated expectation, we have $E_P[\Delta_{A,1}] = 0$. To simplify

the notation, we define

$$\ddot{\psi}_{it}^{a,kl} := \psi^a(W_{it}, \hat{\eta}_{kl}) - \mathbb{E}_P[\psi^a(W_{it}, \hat{\eta}_{kl}) | W(-k, -l)]$$

Then, we have

$$\text{Var} \left(\left\| \hat{A}_{kl} - \mathbb{E}_P[\hat{A}_{kl} | W(-k, -l)] \right\| | W(-k, -l) \right) = \left(\frac{1}{N_k T_l} \right)^2 \mathbb{E}_P \left[\left\| \sum_{i \in I_k, t \in S_l} \ddot{\psi}_{it}^{a,kl} \right\|^2 | W(-k, -l) \right]$$

Expanding $\mathbb{E}_P \left[\left\| \sum_{i \in I_k, t \in S_l} \ddot{\psi}_{it}^{a,kl} \right\|^2 | W(-k, -l) \right]$ and using triangle inequality gives

$$\begin{aligned} & \mathbb{E}_P \left[\left\| \sum_{i \in I_k, t \in S_l} \ddot{\psi}_{it}^{a,kl} \right\|^2 | W(-k, -l) \right] \\ & \leq \sum_{i \in I_k, t \in S_l, r \in S_l} \left| \mathbb{E}_P \left[\langle \ddot{\psi}_{it}^{a,kl}, \ddot{\psi}_{is}^{a,kl} \rangle | W(-k, -l) \right] \right| + \sum_{t \in S_l, i \in I_k, j \in I_k} \left| \mathbb{E}_P \left[\langle \ddot{\psi}_{it}^{a,kl}, \ddot{\psi}_{jt}^{a,kl} \rangle | W(-k, -l) \right] \right| \\ & \quad + \sum_{t \in S_l, i \in I_k} \left| \mathbb{E}_P \left[\langle \ddot{\psi}_{it}^{a,kl}, \ddot{\psi}_{it}^{a,kl} \rangle | W(-k, -l) \right] \right| + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k} \left| \mathbb{E}_P \left[\langle \ddot{\psi}_{it}^{a,kl}, \ddot{\psi}_{j,t+m}^a \rangle | W(-k, -l) \right] \right| \\ & \quad + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i \in I_k} \left| \mathbb{E}_P \left[\langle \ddot{\psi}_{it}^{a,kl}, \ddot{\psi}_{i,t+m}^a \rangle | W(-k, -l) \right] \right| =: a(1) + a(2) + a(3) + 2a(4) + 2a(5). \end{aligned}$$

By conditional Cauchy-Schwarz inequality, for any i, t, j, s , we have

$$\begin{aligned} \left| \mathbb{E}_P \left[\langle \ddot{\psi}_{it}^{a,kl}, \ddot{\psi}_{js}^{a,kl} \rangle | W(-k, -l) \right] \right| & \leq \left(\mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right] \mathbb{E}_P \left[\|\ddot{\psi}_{js}^{a,kl}\|^2 | W(-k, -l) \right] \right)^{1/2} \\ & = \mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right]. \end{aligned}$$

Therefore, we have

$$\begin{aligned} a(1) & \leq N_k T_l^2 \mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right], \\ a(2) & \leq N_k^2 T_l \mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right], \\ a(3) & \leq N_k T_l \mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right], \\ a(5) & \leq N_k T_l^2 \mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right]. \end{aligned}$$

On the event $\mathcal{E}_\eta \cap \mathcal{E}_{cp}$, we have, for $i \in I_k, t \in S_l$,

$$\left(\mathbb{E}_P \left[\|\ddot{\psi}_{it}^{a,kl}\|^2 | W(-k, -l) \right] \right)^{1/2} \lesssim \left(\mathbb{E}_P \left[\|\psi^a(W_{it}, \hat{\eta}_{kl})\|^2 | W(-k, -l) \right] \right)^{1/2} < \infty,$$

where the first inequality follows from expanding the term and applying Jensen's inequality and the second inequality follows from Assumption DML2(i).

Let D denote the dimension of $\psi^a(W, \eta)$, then we have

$$a(4) = a(5) + \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k, i \neq j} \sum_{d=1}^D \mathbb{E}_P \left[\ddot{\psi}_{d,i,t}^{a,kl} \ddot{\psi}_{d,j,t+m}^{a,kl} | W(-k, -l) \right]$$

For each $i \in I_k, t \in S_l$, we can decompose $\ddot{\psi}_{d,i,t}^{a,kl} = a_i^{kl} + g_t^{kl} + e_{it}^{kl}$ where $a_i = \mathbb{E}[\ddot{\psi}_{d,i,t}^{a,kl} | \alpha_i]$, $g_t = \mathbb{E}[\ddot{\psi}_{d,i,t}^{a,kl} | \gamma_t]$, and $e_{it} = \ddot{\psi}_{d,i,t}^{a,kl} - a_i - g_t$. Conditional on $W(-k, -l)$, $(a_i^{kl}, g_t^{kl}, e_{it}^{kl})$ are mutually uncorrelated, $a_i \perp a_j$ for $i \neq j$, and g_t^{kl} is also beta-mixing with $\beta_g(m) \leq \beta_\gamma(m)$, as is shown in the proof of Claim C.3 below. Therefore, we have

$$\begin{aligned} \mathbb{E}_P \left[\ddot{\psi}_{d,i,t}^{a,kl} \ddot{\psi}_{d,j,t+m}^{a,kl} | W(-k, -l) \right] &= \mathbb{E}_P \left[g_t^{kl} g_{t+m}^{kl} + e_{it}^{kl} e_{j,t+m}^{kl} | W(-k, -l) \right] \\ &= \mathbb{E}_P \left[g_t^{kl} g_{t+m}^{kl} | W(-k, -l) \right] + \mathbb{E}_P \left[\mathbb{E}_P \left[e_{it}^{kl} e_{j,t+m}^{kl} | \alpha_i, \alpha_j, W(-k, -l) \right] | W(-k, -l) \right] \end{aligned}$$

Note that β -mixing of γ_t implies α -mixing with the mixing coefficient $\alpha_\gamma(m) \leq \beta_\gamma(m)$ for all $m \in \mathbb{Z}^+$, and conditional on $W(-k, -l)$ and α_i , e_{it}^{kl} is also α -mixing with the mixing coefficient not larger than $\alpha_\gamma(m)$ by Theorem 14.12 of Hansen (2022). Then, we have

$$\begin{aligned} &\left| \mathbb{E}_P \left[\mathbb{E}_P \left[e_{it}^{kl} e_{j,t+m}^{kl} | \alpha_i, \alpha_j, W(-k, -l) \right] | W(-k, -l) \right] \right| \leq \mathbb{E}_P \left[\left| \mathbb{E}_P \left[e_{it}^{kl} e_{j,t+m}^{kl} | \alpha_i, \alpha_j, W(-k, -l) \right] \right| | W(-k, -l) \right] \\ &\lesssim 8\alpha_\gamma(m)^{1-2/q} \left(\mathbb{E}_P[|\ddot{\psi}_{d,i,t}^{a,kl}|^q | W(-k, -l)] \right)^{1/q} \left(\mathbb{E}_P[|\ddot{\psi}_{d,j,t+m}^{a,kl}|^q | W(-k, -l)] \right)^{1/q} \\ &\lesssim 32\alpha_\gamma(m)^{1-2/q} a_1^2, \end{aligned}$$

where the first inequality follows from the Jensen's inequality; the second inequality follows from the fact that $\mathbb{E}[e_{it}^{kl} | \alpha_i, W(-k, -l)] = 0$, and Theorem 14.13(ii) of Hansen (2022); the last inequality follows from the moment conditions in Assumption DML2 and that $W(-k, -l)$ is independent of $W(k, l)$ on \mathcal{E}_{cp} . Similarly,

$$\left| \mathbb{E}_P \left[g_t^{kl} g_{t+m}^{kl} | W(-k, -l) \right] \right| \lesssim \alpha_\gamma(m)^{1-2/q} a_1^2,$$

Then, we have

$$\begin{aligned}
& \frac{1}{N_k^2 T_l} \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k, i \neq j} \sum_{d=1}^D \mathbb{E}_P \left[\ddot{\psi}_{d,i,t}^{a,kl} \ddot{\psi}_{d,j,t+m}^{a,kl} | W(-k, -l) \right] \\
& \lesssim a_1^2 \frac{1}{N_k^2 T_l} \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k, i \neq j} \sum_{d=1}^D \alpha_\gamma(m)^{1-2/q} \\
& \leq a_1^2 D \sum_{m=1}^{\infty} c_\kappa \exp(-\kappa m)^{1-2/q} \leq \frac{a_1^2 D c_\kappa}{\exp(\kappa(1-2/q)) - 1} < \infty,
\end{aligned} \tag{7.9}$$

where the last inequality follows from the geometric sum. Thus, as $(N_k, T_l) \rightarrow \infty$ we have

$$\text{Var} \left(\left\| \hat{A}_{kl} - \mathbb{E}_P[\hat{A}_{kl} | W(-k, -l)] \right\| \right) = \left(\frac{1}{N_k T_l} \right)^2 [a(1) + a(2) + (3) + 2a(4) + 2a(5)] \rightarrow 0.$$

By Chebyshev's inequality, we conclude

$$\left\| \hat{A}_{kl} - \mathbb{E}_P[\hat{A}_{kl} | W(-k, -l)] \right\| = o_P(1).$$

Also note that if we scale $\left\| \hat{A}_{kl} - \mathbb{E}_P[\hat{A}_{kl} | W(-k, -l)] \right\|$ by $N_k^{-1/2}$, it is bounded in probability. So, we can be more specific about the convergence rate:

$$\left\| \hat{A}_{kl} - \mathbb{E}_P[\hat{A}_{kl} | W(-k, -l)] \right\| = O_P(N_k^{-1/2}) = O_P(N^{-1/2}),$$

where the last equality is due to $K < \infty$. To summarize, we have $\left\| \hat{A}_{kl} - A_0 \right\| = O_P(N^{-1/2} + \delta_{NT})$, which implies $\left\| \hat{A} - A_0 \right\| = O_P(N^{-1/2} + r_{NT})$. So, Claim C.1 is proved.

Proof of Claim C.2.

$$\begin{aligned}
& \left\| \hat{\psi}(\theta_0) - \bar{\psi}(\theta_0, \eta_0) \right\| \\
& = \left\| \frac{1}{KL} \sum_{k=1}^K \sum_{l=1}^L \mathbb{E}_{kl}[\psi(W_{it}; \theta_0, \hat{\eta}_{kl})] - \mathbb{E}_{NT}[\psi(W_{it}, \theta_0, \eta_0)] \right\| \\
& = \frac{1}{KL} \left\| \sum_{k=1}^K \sum_{l=1}^L \mathbb{E}_{kl} [\psi(W_{it}; \theta_0, \hat{\eta}_{kl}) - \psi(W_{it}; \theta_0, \eta_0)] \right\|
\end{aligned}$$

Since K and L are finite, it suffices to show

$$\left\| \mathbb{E}_{kl} [\psi(W_{it}; \theta_0, \hat{\eta}_{kl}) - \psi(W_{it}; \theta_0, \eta_0)] \right\| = O_P(r'_{NT} / \sqrt{N_k} + \lambda_{NT} + \lambda'_{NT}).$$

We also define

$$\ddot{\psi}_{it}^{kl} := \psi(W_{it}; \theta_0, \hat{\eta}_{kl}) - \psi(W_{it}; \theta_0, \eta_0),$$

and define

$$\begin{aligned} b(1) &:= \left\| \frac{\sqrt{N_k}}{N_k T_l} \sum_{i \in I_k, t \in S_l} [\ddot{\psi}_{it}^{kl} - \mathbb{E}_P[\ddot{\psi}_{it}^{kl} | W(-k, -l)]] \right\| \\ b(2) &:= \left\| \mathbb{E}_P [\psi(W_{it}; \theta_0, \hat{\eta}_{kl}) | W(-k, -l)] - \mathbb{E}_P [\psi(W_{it}; \theta_0, \eta_0)] \right\|. \end{aligned}$$

Then, by triangle inequality we have

$$\left\| \mathbb{E}_{kl} [\psi(W_{it}; \theta_0, \hat{\eta}_{kl}) - \psi(W_{it}; \theta_0, \eta_0)] \right\| \leq b(1)/\sqrt{N_k} + b(2).$$

To bound $b(1)$, first note that it is mean zero by the iterated expectation argument. We further define

$$\tilde{\psi}_{it}^{kl} := \ddot{\psi}_{it}^{kl} - \mathbb{E}_P[\ddot{\psi}_{it}^{kl} | W(-k, -l)],$$

and denote $\tilde{\psi}_{d,it}$ as each element in the vector $\tilde{\psi}_{it}^{kl}$ for $d = 1, \dots, D$, while still suppressing the subscripts k, l for convenience. Similar to what we have shown in the proof of Claim C.1, on the event $\mathcal{E}_\eta \cap \mathcal{E}_{cp}$, we have

$$\begin{aligned} \mathbb{E}_P[b(1)^2 | W(-k, -l)] &\leq \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \left| \mathbb{E}_P [\langle \tilde{\psi}_{it}^{kl}, \tilde{\psi}_{is}^{kl} \rangle | W(-k, -l)] \right| \\ &\quad + \frac{1}{N_k T_l^2} \sum_{t \in S_l, i \in I_k, j \in I_k} \left| \mathbb{E}_P [\langle \tilde{\psi}_{it}^{kl}, \tilde{\psi}_{jt}^{kl} \rangle | W(-k, -l)] \right| \\ &\quad + \frac{1}{N_k T_l^2} \sum_{t \in S_l, i \in I_k} \left| \mathbb{E}_P [\langle \tilde{\psi}_{it}^{kl}, \tilde{\psi}_{it}^{kl} \rangle | W(-k, -l)] \right| \\ &\quad + 2 \frac{1}{N_k T_l^2} \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k} \left| \mathbb{E}_P [\langle \tilde{\psi}_{it}^{kl}, \tilde{\psi}_{j,t+m}^{kl} \rangle | W(-k, -l)] \right| \\ &\quad + 2 \frac{1}{N_k T_l^2} \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i \in I_k} \left| \mathbb{E}_P [\langle \tilde{\psi}_{it}^{kl}, \tilde{\psi}_{i,t+m}^{kl} \rangle | W(-k, -l)] \right| \\ &=: c(1) + c(2) + c(3) + 2c(4) + 2c(5). \end{aligned}$$

By conditional Cauchy-Schwarz inequality, for any i, t, j, s , we have

$$\left| \mathbb{E}_P [\langle \tilde{\psi}_{it}^{kl}, \tilde{\psi}_{js}^{kl} \rangle | W(-k, -l)] \right| \leq \left(\mathbb{E}_P [\|\tilde{\psi}_{it}^{kl}\|^2 | W(-k, -l)] \mathbb{E}_P [\|\tilde{\psi}_{js}^{kl}\|^2 | W(-k, -l)] \right)^{1/2}.$$

Applying Minkowski's inequality, Jensen's inequality on the event $\mathcal{E}_\eta \cap \mathcal{E}_{cp}$, we have, for $i \in I_k, t \in S_l$,

$$\begin{aligned} (\mathbb{E}_P [\|\tilde{\psi}_{it}^{kl}\|^2 | W(-k, -l)])^{1/2} &\leq (\mathbb{E}_P [\|\ddot{\psi}_{it}^{kl}\|^2 | W(-k, -l)])^{1/2} + (\mathbb{E}_P [\|\mathbb{E}_P[\ddot{\psi}_{it}^{kl} | W(-k, -l)]\|^2 | W(-k, -l)])^{1/2} \\ &\leq 2 (\mathbb{E}_P [\|\ddot{\psi}_{it}^{kl}\|^2 | W(-k, -l)])^{1/2} \\ &\leq 2r'_{NT}. \end{aligned}$$

Therefore, we have

$$\begin{aligned} c(1) &\leq \mathbb{E}_P [\|\tilde{\psi}_{it}^{kl}\|^2 | W(-k, -l)] = O(r'_{NT}{}^2), \\ c(2) &\leq c \mathbb{E}_P [\|\tilde{\psi}_{it}^{kl}\|^2 | W(-k, -l)] = O(r'_{NT}{}^2), \\ c(3) &\leq \frac{1}{N_k} \mathbb{E}_P [\|\tilde{\psi}_{it}^{kl}\|^2 | W(-k, -l)] = O(r'_{NT}{}^2 / N), \\ c(5) &\leq \mathbb{E}_P [\|\tilde{\psi}_{it}^{kl}\|^2 | W(-k, -l)] = O(r'_{NT}{}^2). \end{aligned}$$

Following similar arguments as 7.9, $c(4)$ is of order $O(r'_{NT}{}^2)$. So, we have shown

$$\mathbb{E}_P[b(1)^2 | W(-k, -l)] = O(r'_{NT}{}^2),$$

which implies $b(1) = O_P(r'_{NT})$.

To bound $b(2)$, we first define

$$f_{kl}(r) := \mathbb{E}_P [\psi(W_{it}, \theta_0, \eta_0 + r(\hat{\eta}_{kl} - \eta_0) | W(-k, -l)] - \mathbb{E}_P [\psi(W_{it}; \theta_0, \eta_0)], \quad r \in [0, 1],$$

for some $i \in I_k, t \in S_l$. So, $b(2) = \|f_{kl}(1)\|$. By expanding $f_{kl}(r)$ around 0 using mean value theorem and evaluating at $r = 1$, we have

$$f_{kl}(r) = f_{kl}(0) + f'_{kl}(0) + f''_{kl}(\tilde{r})/2,$$

where $\tilde{r} \in (0, 1)$. We note that $f_{kl}(0) = 0$ on the event \mathcal{E}_{cp} . On the event $\mathcal{E}_\eta \cap \mathcal{E}_{cp}$, we have

$$\|f'_{kl}(0)\| \leq \lambda_{NT},$$

under Assumption DML1(ii)(near-orthogonality), and

$$\|f''_{kl(0)}\| \leq \lambda'_{NT}.$$

Therefore, we have shown that $b(2) = O_P(\lambda_{NT}) + O_P(\lambda'_{NT})$. Combining the bounds for $b(1)$ and $b(2)$ completes the proof of Claim C.2.

Proof of Claim C.3. Following the decomposition approach taken in Chiang et al. (2024), we define the

following terms

$$\begin{aligned} a_i &:= \mathbb{E}_P [\psi (W_{it}; \theta_0, \eta_0) | \alpha_i], \\ g_t &:= \mathbb{E}_P [\psi (W_{it}; \theta_0, \eta_0) | \gamma_t], \\ e_{it} &:= \psi (W_{it}; \theta_0, \eta_0) - a_i - g_t. \end{aligned}$$

Then, we can rewrite $\psi (W_{it}; \theta_0, \eta_0) = a_i + g_t + e_{it}$. Under Assumptions 2 and 2, the decomposition has the following properties:

- (i) $\{a_i\}_{i \geq 1}$ is a sequence of i.i.d random vectors, $\{g_t\}_{t \geq 1}$ are strictly stationary and β -mixing with the mixing coefficient $\beta_g(m) \leq \beta_\gamma(m)$ for all $m \geq 1$; for each i , $\{e_{it}\}_{t \geq 1}$ is also strictly stationary; and a_i is independent of g_t .
- (ii) a_i, b_t, e_{it} are mean zero.
- (iii) Conditional on (γ_t, γ_r) , e_{it} and e_{jr} are independent for $j \neq i$.
- (iv) The sequences $\{a_i\}, \{g_t\}, \{e_{it}\}$ are mutually uncorrelated.

Properties (i) and (ii) are straightforward. Property (iii) is due to the assumption that $\{\alpha_i\}$ and $\{\varepsilon_{it}\}$ are each i.i.d sequence and independent of each other. Property (iv) is less obvious. One can show $\mathbb{E}_P[e_{it}|\gamma_r] = 0$ and $\mathbb{E}_P[e_{it}|\alpha_j]$ for any i, t, j, r . It is less obvious to see $\mathbb{E}_P[e_{it}|\gamma_r] = 0$ for some $r \neq t$:

$$\begin{aligned} \mathbb{E}_P[e_{it}|\gamma_r] &= \mathbb{E}_P[\psi (W_{it}; \theta_0, \eta_0) | \gamma_r] - \mathbb{E}_P[a_i|\gamma_r] - \mathbb{E}_P[g_t|\gamma_r] \\ &= \mathbb{E}_P[\mathbb{E}_P[\psi (f(\alpha_i, \gamma_t, \varepsilon_{it}); \theta_0, \eta_0) | \gamma_t, \gamma_r] | \gamma_r] - \mathbb{E}_P[a_i] - \mathbb{E}_P[g_t|\gamma_r] \\ &= \mathbb{E}_P[\mathbb{E}_P[\psi (f(\alpha_i, \gamma_t, \varepsilon_{it}); \theta_0, \eta_0) | \gamma_t] | \gamma_r] - \mathbb{E}_P[a_i] - \mathbb{E}_P[g_t|\gamma_r] \\ &= \mathbb{E}_P[g_t|\gamma_r] - \mathbb{E}_P[g_t|\gamma_r] = 0 \end{aligned}$$

where the second equality follows from the iterated expectation and the independence of α_i and γ_r and the third equality follows from that given γ_t, γ_r is independent of $(\alpha_i, \gamma_t, \varepsilon_{it})$.

With the decomposition, we can re-express $\sqrt{N}\bar{\psi}(\theta_0, \eta_0)$ as follows:

$$\sqrt{N}\bar{\psi}(\theta_0, \eta_0) = \frac{1}{\sqrt{N}} \sum_{i=1}^N a_i + \frac{\sqrt{c}}{\sqrt{T}} \sum_{t=1}^T g_t + \frac{1}{\sqrt{NT}} \sum_{i=1}^N \sum_{t=1}^T e_{it}$$

Since the summations on the RHS are mutually uncorrelated, we have

$$\begin{aligned} \text{Var} \left(\sqrt{N}\bar{\psi}(\theta_0, \eta_0) \right) &= \text{Var} \left(\frac{1}{\sqrt{N}} \sum_{i=1}^N a_i \right) + \text{Var} \left(\frac{\sqrt{c}}{\sqrt{T}} \sum_{t=1}^T g_t \right) + \text{Var} \left(\frac{1}{\sqrt{NT}} \sum_{i=1}^N \sum_{t=1}^T e_{it} \right) \\ &= \Lambda_a \Lambda'_a + c \left(\Lambda_g \Lambda'_g + o(1) \right) + \frac{c}{N} \left(\Lambda_e \Lambda'_e + o(1) \right), \end{aligned}$$

where the second equality follows from the stationarity of g_t and e_{it} , the uncorrelatedness of e_{it} over i , and

the moment condition on $\psi(W_{it}; \theta_0, \eta_0)$ (Assumption DML2(i)).

Next, we will show $\|\Lambda_a \Lambda'_a\| < \infty$, $\|\Lambda_g \Lambda'_g\| < \infty$, $\|\Lambda_e \Lambda'_e\| < \infty$. With an application of (conditional) Jensen's inequality and under Assumption DML2, we have

$$\begin{aligned} \|\Lambda_a \Lambda'_a\| &= \|\mathbb{E}_P[a'_i a_i]\| \leq \mathbb{E}_P\|a_i a'_i\| = \mathbb{E}_P\|a_i\|^2 = \mathbb{E}_P\|\mathbb{E}_P[\psi(W_{it}; \theta_0, \eta_0) | \alpha_i]\|^2 \\ &\leq \mathbb{E}_P[\mathbb{E}_P\|\psi(W_{it}; \theta_0, \eta_0)\|^2 | \alpha_i] = \mathbb{E}_P\|\psi(W_{it}; \theta_0, \eta_0)\|^2 \leq m_{NT} < \infty. \end{aligned}$$

Due to the β -mixing property of g_t , we have

$$\begin{aligned} \|\Lambda_g \Lambda'_g\| &= \left\| \sum_{q=-\infty}^{\infty} \mathbb{E}_P[g_t g'_{t+q}] \right\| \leq \|\mathbb{E}_P[g_t g'_t]\| + 2 \sum_{q=1}^{\infty} \|\mathbb{E}_P[g_t g'_{t+q}]\| \\ &\leq \mathbb{E}_P\|\psi(W_{it}; \theta_0, \eta_0)\|^2 + 16 (\mathbb{E}_P\|g_t\|^q)^{2/q} \sum_{q=1}^{\infty} \beta_g(q)^{1-2/q} \leq \infty \end{aligned}$$

where the second inequality follows Theorem 14.13(ii) of Hansen (2022) (with the α -mixing coefficient replaced by the β -mixing coefficient) and the third inequality follows from Assumptions 2 and DML2 with $p > 2$.

Note that, conditional on α_i , e_{it} is also β -mixing with the same mixing coefficient as γ_t . So, by Jensen's inequality, Theorem 14.13(ii), and again Jensen's inequality, we have

$$\left\| \mathbb{E}_P[e_{it} e_{i,t+q}] \right\| \leq \mathbb{E}_P \left\| \mathbb{E}_P[e_{it} e_{i,t+q} | \alpha_i] \right\| \leq 8 (\mathbb{E}_P\|e_{it}\|^q)^{2/q} \alpha_g(q)^{1-2/q}. \quad (7.10)$$

Then, similarly, we have

$$\|\Lambda_e \Lambda'_e\| = \left\| \sum_{q=-\infty}^{\infty} \mathbb{E}_P[e_{it} e'_{i,t+q}] \right\| < \infty.$$

Then, as $N, T \rightarrow \infty$, we have

$$\text{Var} \left(\sqrt{N} \bar{\psi}(\theta_0, \eta_0) \right) \rightarrow \Lambda_a \Lambda'_a + c \Lambda_g \Lambda'_g = \Omega.$$

We have shown $\{a_i\}_{i \geq 1}$ is a sequence of i.i.d random vector with mean zero and finite variance $\Lambda_a \Lambda'_a$. Then, Lindeberg-Lévy CLT applies:

$$\frac{1}{\sqrt{N}} \sum_{i=1}^N a_i \xrightarrow{d} N(0, \Lambda_a \Lambda'_a).$$

Note that g_t is mean zero, $\mathbb{E}_P\|g_t\|^2 < \infty$, strictly stationary and β -mixing. Previously, we have shown $\sum_{q=1}^{\infty} \beta_g(q)^{1-2/q} < \infty$ for some $p > 2$. Then, the central limit theorem for mixing sequences applies here

(see Theorem 14.15 of Hansen (2022)):

$$\frac{1}{\sqrt{T}} \sum_{t=1}^T \sum_{i=1}^T g_t \xrightarrow{d} N(0, \Lambda_g \Lambda_g')$$

Lastly, $\|\Lambda_e \Lambda_e'\| < \infty$ implies $\text{Var} \left(\frac{1}{\sqrt{NT}} \sum_{i=1}^N \sum_{t=1}^T e_{it} \right) \rightarrow 0$. By Chebyshev's inequality, we have each component of the vector $\frac{1}{\sqrt{NT}} \sum_{i=1}^N \sum_{t=1}^T e_{it} \xrightarrow{p} 0$, and so

$$\frac{1}{\sqrt{NT}} \sum_{i=1}^N \sum_{t=1}^T e_{it} \xrightarrow{p} 0.$$

Since $\{a_i\}_{i \geq 1}$ and $\{g_t\}_{t \geq 1}$ are independent, we have $\frac{1}{\sqrt{N}} \sum_{i=1}^N a_i + \frac{\sqrt{c}}{\sqrt{T}} \sum_{t=1}^T g_t \xrightarrow{d} N(0, \Lambda_a \Lambda_a' + c \Lambda_g \Lambda_g') = N(0, \Omega)$. Therefore, as $N, T \rightarrow \infty$, we have

$$\sqrt{N} \tilde{\psi}(\theta_0, \eta_0) \xrightarrow{d} N(0, \Omega),$$

as claimed. □

Proof of Theorem 3.2. By the same arguments as at the beginning of the proof of Theorem 3.1, we have $P(\mathcal{E}_\eta \cap \mathcal{E}_{cp}) = 1 - P(\mathcal{E}_\eta^c \cup \mathcal{E}_{cp}^c) \geq 1 - o(1)$. By Claim C.1, we have $\|\hat{A} - A_0\| = O_P(N^{-1/2} + r_{NT})$ on event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$. Therefore, due to $\|A_0^{-1}\| \leq a_0^{-1}$ ensured by Assumption DML1(iv) and $\Omega < \infty$ as shown in Claim C.2, it suffices to show $\|\hat{\Omega}_{\text{CHS}} - \Omega\| = o_P(1)$. Furthermore, since K, L are fixed constants, it suffices to show for each (k, l) that $\|\hat{\Omega}_{\text{CHS}, kl} - \Omega\| = o_P(1)$ where

$$\begin{aligned} \hat{\Omega}_{\text{CHS}, kl} &:= \hat{\Omega}_{a, kl} + \hat{\Omega}_{b, kl} - \hat{\Omega}_{c, kl} + \hat{\Omega}_{d, kl} + \hat{\Omega}'_{d, kl}, \\ \hat{\Omega}_{a, kl} &:= \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{ir}; \hat{\theta}, \hat{\eta}_{kl})', \\ \hat{\Omega}_{b, kl} &:= \frac{K/L}{N_k T_l^2} \sum_{t \in S_l, i \in I_k, j \in I_k} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{jt}; \hat{\theta}, \hat{\eta}_{kl})', \\ \hat{\Omega}_{c, kl} &:= \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl})', \\ \hat{\Omega}_{d, kl} &:= \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \sum_{t=\lfloor S_l \rfloor}^{\lfloor S_l \rfloor - m} \sum_{i \in I_k, j \in I_k, j \neq i} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{j, t+m}; \hat{\theta}, \hat{\eta}_{kl})'. \end{aligned}$$

Since a sequence of symmetric matrices Ω_n converges to a symmetric matrix Ω_0 if and only if $e' \Omega_n e \rightarrow e' \Omega_0 e$ for all comfortable e , it suffices to assume without loss of generality that the dimension of ψ to be 1.

To simplify the expression, we define

$$\psi_{it}^{(0)} = \psi(W_{it}; \theta_0, \eta_0), \quad \hat{\psi}_{it}^{(kl)} = \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl})$$

Claim C.4. On event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, $|\hat{\Omega}_{a,kl} - \Lambda_a \Lambda_a| = O_P(N^{-1/2} + r'_{NT})$.

Claim C.5. On event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, $|\hat{\Omega}_{b,kl} - cE_P[g_t g_t]| = O_P(N^{-1/2} + r'_{NT})$.

Claim C.6. On event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, $|\hat{\Omega}_{c,kl}| = O_P(T^{-1})$.

Claim C.7. On event $\{\mathcal{E}_\eta \cap \mathcal{E}_{cp}\}$, $|\hat{\Omega}_{d,kl} - c \sum_{m=1}^{\infty} E_P[g_t g_{t+m}]| = o_P(1)$.

The decomposition techniques used in the proofs of Claims A.4, A.5, and A.7 follow the proofs of Lemma 1 and Lemma 2 in Appendix E of Chiang et al. (2024). Combining the Claims A.4-A.7 completes the proof of Theorem 3.2.

Proof of Claim C.4. By triangle inequality, we have

$$|\hat{\Omega}_{a,kl} - \Lambda_a \Lambda_a'| \leq |I_{a,1}^{(kl)}| + |I_{a,2}^{(kl)}| + |I_{a,3}^{(kl)}|,$$

where

$$\begin{aligned} I_{a,1}^{(kl)} &:= \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \left\{ \hat{\psi}_{it}^{(kl)} \hat{\psi}_{ir}^{(kl)} - \psi_{it}^{(0)} \psi_{ir}^{(0)} \right\}, \\ I_{a,2}^{(kl)} &:= \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \left\{ \psi_{it}^{(0)} \psi_{ir}^{(0)} - E_P[\psi_{it}^{(0)} \psi_{ir}^{(0)}] \right\}, \\ I_{a,3}^{(kl)} &:= \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} E_P[\psi_{it}^{(0)} \psi_{ir}^{(0)}] - E_P[a_i a_i]. \end{aligned}$$

By law of total covariance and mean-zero property of $\psi_{it}^{(0)}$, we have

$$E_P \left[\psi_{it}^{(0)} \psi_{ir}^{(0)} \right] = E_P[E_P(\psi_{it}^{(0)}, \psi_{ir}^{(0)} | \alpha_i)] + E_P \left(E_P[\psi_{it}^{(0)} | \alpha_i] E_P[\psi_{ir}^{(0)} | \alpha_i] \right)$$

Due to the identical distribution of α_i and mean zero, we have

$$\frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} E_P[\psi_{it}^{(0)} \psi_{ir}^{(0)}] = \frac{1}{T_l^2} \sum_{t \in S_l, r \in S_l} \left\{ E_P[E_P(\psi_{it}^{(0)} \psi_{ir}^{(0)} | \alpha_i)] + E_P(E_P[\psi_{it}^{(0)} | \alpha_i] E_P[\psi_{ir}^{(0)} | \alpha_i]) \right\}$$

Conditional on α_i , $\{\psi_{it}^{(0)}\}_{t \geq 1}$ is β -mixing with the mixing coefficient same as γ_t . Therefore, we can apply Theorem 14.13(ii) in Hansen (2022) and Jensen's inequality:

$$E_P \left| E_P \left[\psi_{it}^{(0)}, \psi_{ir}^{(0)} | \alpha_i \right] \right| \leq 8 \left(E_P |\psi_{it}^{(0)}|^q \right)^{2/q} \beta_\gamma(|t - r|)^{1-2/q}$$

Note that $\sum_{t \in S_l, r \in S_l} \beta_\gamma(|t-r|)^{1-2/q} \leq \infty$ under Assumption 2. So, $I_{a,3}^{(kl)} = O(1/T_l^2) = O(T^{-2})$.

To bound $I_{a,2}^{(kl)}$, we can rewrite it by triangle inequality as follows:

$$\left| I_{a,2}^{(kl)} \right| \leq \left| \frac{1}{N_k} \sum_{i \in I_k} I_{a,2,i}^{(kl)} \right| + \left| \frac{1}{N_k} \sum_{i \in I_k} \tilde{I}_{a,2,i}^{(kl)} \right|,$$

where

$$\begin{aligned} I_{a,2,i}^{(kl)} &:= \frac{1}{T_l^2} \sum_{t,r \in S_l} \left\{ \psi_{it}^{(0)} \psi_{ir}^{(0)} - \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{ir}^{(0)} | \{\gamma_t\}_{t \in S_l} \right] \right\}, \\ \tilde{I}_{a,2,i}^{(kl)} &:= \frac{1}{T_l^2} \sum_{t,r \in S_l} \left\{ \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{ir}^{(0)} | \{\gamma_t\}_{t \in S_l} \right] - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{ir}^{(0)}] \right\}. \end{aligned}$$

Due to identical distribution of α_i , $\tilde{I}_{a,2,i}^{(kl)}$ does not vary over i so that $\mathbb{E}_P \left| \frac{1}{N_k} \sum_{i \in I_k} \tilde{I}_{a,2,i}^{(kl)} \right|^2 = \mathbb{E}_P \left| \tilde{I}_{a,2,i}^{(kl)} \right|^2$. Denote $h_i(\gamma_t, \gamma_r) = \mathbb{E}_P[\psi_{it}^{(0)} \psi_{ir}^{(0)} | \gamma_t, \gamma_r] - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{ir}^{(0)}]$. By direct calculation, we have

$$\mathbb{E}_P \left| \tilde{I}_{a,2,i}^{(kl)} \right|^2 = \frac{1}{T_l^4} \sum_{t,r,t',r' \in S_l} \mathbb{E}_P \left[h_i(\gamma_t, \gamma_r) h_i(\gamma_{t'}, \gamma_{r'}) \right].$$

To bound the RHS above, we can apply Lemma 3.4 in Dehling and Wendler (2010) by verifying the following two conditions:

$$\mathbb{E}_P \left| h_i(\gamma_t, \gamma_r) \right|^{2+\delta} < \infty, \quad (7.11)$$

$$\int \int \left| h_i(u, v) \right|^{2+\delta} dF(u) dF(v) < \infty, \quad (7.12)$$

for some $\delta > 0$ and $F(\cdot)$ is the common CDF of γ_t .

Consider condition 7.11. By Minkowski's inequality, Jensen's inequality, and the law of iterated expectation, we have

$$\begin{aligned} \left(\mathbb{E}_P \left| h_i(\gamma_t, \gamma_r) \right|^{2+\delta} \right)^{\frac{1}{2+\delta}} &\leq \left(\mathbb{E}_P \left| \psi_{it}^{(0)} \psi_{ir}^{(0)} \right|^{2+\delta} \right)^{\frac{1}{2+\delta}} + \mathbb{E}_P \left| \psi_{it}^{(0)} \psi_{ir}^{(0)} \right| \\ &\leq \left(\mathbb{E}_P \left| \psi_{it}^{(0)} \right|^{4+2\delta} \right)^{\frac{1}{2+\delta}} + \mathbb{E}_P \left| \psi_{it}^{(0)} \right|^2 \end{aligned}$$

where the second inequality follows from Hölder's inequality and the identical distribution of γ_t . Let $\delta = \frac{p-4}{2}$,

then $\left(\mathbb{E}_P \left| \psi_{it}^{(0)} \right|^{4+2\delta} \right)^{\frac{1}{2+\delta}} < a_1$ and $\mathbb{E}_P \left| \psi_{it}^{(0)} \right|^2 \leq a_1^2$ follows from Assumption DML2(i). Therefore, condition 7.11 is satisfied.

Consider condition 7.12. By Minkowski's inequality and Jensen's inequality, we have

$$\begin{aligned}
& \left(\int \int \left| \mathbb{E}_P[\psi_{it}^{(0)} \psi_{ir}^{(0)} | \gamma_t = u, \gamma_r = v] - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{ir}^{(0)}] \right|^{2+\delta} dF(u) dF(v) \right)^{\frac{1}{2+\delta}} \\
& \leq \left(\int \int \left| \mathbb{E}_P[\psi_{it}^{(0)} \psi_{ir}^{(0)} | \gamma_t = u, \gamma_r = v] \right|^{2+\delta} dF(u) dF(v) \right)^{\frac{1}{2+\delta}} + \mathbb{E}_P \left| \psi_{it}^{(0)} \psi_{ir}^{(0)} \right| \\
& \leq \left(\int \int \left(\mathbb{E}_P \left[\left| \psi_{it}^{(0)} \right|^2 | \gamma_t = u \right] \right)^{\frac{2+\delta}{2}} \left(\mathbb{E}_P \left[\left| \psi_{ir}^{(0)} \right|^2 | \gamma_r = v \right] \right)^{\frac{2+\delta}{2}} dF(u) dF(v) \right)^{\frac{1}{2+\delta}} + \mathbb{E}_P \left| \psi_{it}^{(0)} \right|^2 \\
& \leq \left(\int \int \mathbb{E}_P \left[\left| \psi_{it}^{(0)} \right|^{2+\delta} | \gamma_t = u \right] \mathbb{E}_P \left[\left| \psi_{ir}^{(0)} \right|^{2+\delta} | \gamma_r = v \right] dF(u) dF(v) \right)^{\frac{1}{2+\delta}} + \mathbb{E}_P \left| \psi_{it}^{(0)} \right|^2 \\
& = \left(\mathbb{E}_P \left| \psi_{it}^{(0)} \right|^{4+2\delta} \right)^{\frac{1}{2+\delta}} + \mathbb{E}_P \left| \psi_{it}^{(0)} \right|^2
\end{aligned}$$

where the second inequality follows from (conditional) Hölder's inequality and identical distribution of γ_t ; the third inequality follows from Jensen's inequality; the last equality follows from the law of iterated expectation and the identical distribution of γ_t . Therefore, condition 7.12 is also satisfied with $\delta = \frac{p-4}{2}$. By Lemma 3.4 in Dehling and Wendler (2010), we conclude

$$\mathbb{E}_P \left| \tilde{I}_{a,2,i}^{(kl)} \right|^2 = \frac{1}{T_l^4} \sum_{t,r,t',r' \in S_l} \mathbb{E}_P \left[h_i(\gamma_t, \gamma_r) h_i(\gamma_{t'}, \gamma_{r'}) \right] = o(T_l^{-1}) = o(T^{-1}).$$

Therefore, by Markov inequality, we have $\tilde{I}_{a,2,i}^{(kl)} = o_P(T^{-1/2})$.

Consider $\left| \frac{1}{N_k} \sum_{i \in I_k} I_{a,2,i}^{(kl)} \right|$. Note that conditional on $\{\gamma_t\}_{t \in S_l}$, $I_{a,2,i}^{(kl)}$ is i.i.d over i . So, we have

$$\begin{aligned}
\mathbb{E}_P \left[\left| \frac{1}{N_k} \sum_{i \in I_k} I_{a,2,i}^{(kl)} \right|^2 | \{\gamma_t\}_{t \in S_l} \right] &= \frac{1}{N_k^2} \sum_{i \in I_k} \mathbb{E}_P \left[\left| I_{a,2,i}^{(kl)} \right|^2 | \{\gamma_t\}_{t \in S_l} \right] \\
&= \frac{1}{N_k} \mathbb{E}_P \left[\left| I_{a,2,i}^{(kl)} \right|^2 | \{\gamma_t\}_{t \in S_l} \right]
\end{aligned}$$

By conditional Markov inequality, we have

$$\mathbb{P} \left(\left| \frac{1}{N_k} \sum_{i \in I_k} I_{a,2,i}^{(kl)} \right| > \varepsilon | \{\gamma_t\}_{t \in S_l} \right) = O \left(\frac{1}{N_k} \mathbb{E}_P \left[\left| I_{a,2,i}^{(kl)} \right|^2 | \{\gamma_t\}_{t \in S_l} \right] \right)$$

By Minkowski's inequality for infinite sums, Jensen's inequality, and Hölder's inequality, we have

$$\begin{aligned} \left(\mathbb{E}_P \left[\left| I_{a,2,i}^{(kl)} \right|^2 \right] \right)^{1/2} &\lesssim \frac{1}{T_l^2} \sum_{t,r \in S_l} \left(\mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{ir}^{(0)} \right]^2 \right)^{1/2} \\ &\leq \frac{1}{T_l^2} \sum_{t,r \in S_l} \left(\mathbb{E}_P \left[\psi_{it}^{(0)} \right]^4 \right)^{1/2} \leq a_1^2, \end{aligned}$$

where the last inequality follows from Assumption 3.5(ii). Then, by law of iterated expectation, we have

$$\mathbb{P} \left(\left| \frac{1}{N_k} \sum_{i \in I_k} I_{a,2,i}^{(kl)} \right| > \varepsilon \right) = O(N_k^{-1}),$$

and $\left| \frac{1}{N_k} \sum_{i \in I_k} I_{a,2,i}^{(kl)} \right| = O_P(N_k^{-1/2}) = O_P(N^{-1/2})$. Therefore, we have shown $I_{a,2}^{kl} = O_P(N^{-1/2}) + o_P(T^{-1/2})$.

Now, consider $I_{a,1}^{kl}$.

$$\begin{aligned} |I_{a,1}^{kl}| &\leq \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \left| \hat{\psi}_{it}^{(kl)} \hat{\psi}_{ir}^{(kl)'} - \psi_{it}^{(0)} \psi_{ir}^{(0)} \right| \\ &\leq \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \left\{ \left| \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right) \left(\hat{\psi}_{ir}^{(kl)} - \psi_{ir}^{(0)} \right) \right| + \left| \psi_{it}^{(0)} \left(\hat{\psi}_{ir}^{(kl)} - \psi_{ir}^{(0)} \right) \right| + \left| \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right) \hat{\psi}_{ir}^{(kl)'} \right| \right\} \\ &\leq \frac{1}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} \left\{ \left| \hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right| \left| \hat{\psi}_{ir}^{(kl)} - \psi_{ir}^{(0)} \right| + \left| \psi_{it}^{(0)} \right| \left| \hat{\psi}_{ir}^{(kl)} - \psi_{ir}^{(0)} \right| + \left| \hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right| \left| \hat{\psi}_{ir}^{(kl)'} \right| \right\} \\ &\leq \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right)^2 \right)^{1/2} \left(\frac{1}{N_k T_l} \sum_{i \in I_k, r \in S_l} \left(\hat{\psi}_{ir}^{(kl)} - \psi_{ir}^{(0)} \right)^2 \right)^{1/2} \\ &\quad + \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 \right)^{1/2} \left(\frac{1}{N_k T_l} \sum_{i \in I_k, r \in S_l} \left(\hat{\psi}_{ir}^{(kl)} - \psi_{ir}^{(0)} \right)^2 \right)^{1/2} \\ &\quad + \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right)^2 \right)^{1/2} \left(\frac{1}{N_k T_l} \sum_{i \in I_k, r \in S_l} \left(\psi_{ir}^{(0)} \right)^2 \right)^{1/2}, \\ &\lesssim R_{kl} \left\{ \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 \right)^{1/2} + R_{kl} \right\}, \end{aligned}$$

where

$$R_{kl} = \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right)^2 \right)^{1/2}.$$

By Markov inequality and under Assumption DML2(i), we have

$$\mathbb{E}_P \left[\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 \right] = \mathbb{E}_P \left| \psi(W_{it}; \theta_0, \eta_0) \right|^2 \leq a_1^2.$$

Therefore, $\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 = O_P(1)$. To bound R_{kl} , note that by Assumption DML1(i) (linearity) we have

$$\begin{aligned} R_{kl}^2 &= \frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi^a(W_{it}; \hat{\eta}_{kl})(\hat{\theta} - \theta_0) + \psi(W_{it}; \theta_0, \hat{\eta}_{kl}) - \psi(W_{it}; \theta_0, \eta_0) \right)^2 \\ &\lesssim \frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left| \psi^a(W_{it}; \hat{\eta}_{kl}) \right|^2 \left| \hat{\theta} - \theta_0 \right|^2 + \frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left| \hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right|^2 \end{aligned}$$

By Markov inequality and Assumption DML2(i), we have $\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left| \psi^a(W_{it}; \hat{\eta}_{kl}) \right|^2 = O_P(1)$. By Theorem 3.1, $\left| \hat{\theta} - \theta_0 \right|^2 = O_P(N^{-1})$. Therefore, the first term on RHS is $O_P(N^{-1})$. For the second term on RHS, consider its conditional expectation given the auxiliary sample $W(-k, -l)$. On the event $\mathcal{E}_\eta \cap \mathcal{E}_{cp}$, we have

$$\begin{aligned} &\mathbb{E}_P \left[\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left| \hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right|^2 \mid W(-k, -l) \right] \\ &= \mathbb{E}_P \left[\left| \psi(W_{it}; \theta_0, \hat{\eta}_{kl}) - \psi(W_{it}; \theta_0, \eta_0) \right|^2 \mid W(-k, -l) \right] \leq (\delta'_{NT})^2, \end{aligned}$$

where the last inequality follows from Assumption DML2(ii). Then, by Markov inequality, we have $R_{kl}^2 = O_P(N^{-1} + (r'_{NT})^2)$ and so $\left| I_{a,1}^{kl} \right| = O_P(N^{-1/2} + r'_{NT})$. To summarize, we have shown

$$\left| \hat{\Omega}_{a,kl} - \Lambda_a \Lambda'_a \right| = O_P(N^{-1/2} + r'_{NT}) + O_P(N^{-1/2}) + o_P(T^{-1/2}) + O(T^{-2}) = O_P(N^{-1/2} + r'_{NT})$$

Proof of Claim C.5. By triangle inequality, we have

$$\left| \hat{\Omega}_{b,kl} - c \mathbb{E}_P[g_t g'_t] \right| \leq \left| I_{b,1}^{(kl)} \right| + \left| I_{b,2}^{(kl)} \right| + \left| I_{b,3}^{(kl)} \right|,$$

where

$$\begin{aligned} I_{b,1}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{t \in S_l, i \in I_k, j \in I_k} \left\{ \hat{\psi}_{it}^{(kl)} \hat{\psi}_{jt}^{(kl)} - \psi_{it}^{(0)} \psi_{jt}^{(0)} \right\}, \\ I_{b,2}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{t \in S_l, i \in I_k, j \in I_k} \left\{ \psi_{it}^{(0)} \psi_{jt}^{(0)} - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{jt}^{(0)}] \right\}, \\ I_{b,3}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{t \in S_l, i \in I_k, j \in I_k} \mathbb{E}_P[\psi_{it}^{(0)} \psi_{jt}^{(0)}] - c \mathbb{E}_P[g_t g'_t], \end{aligned}$$

and $\frac{K/L}{N_k T_l^2} = \frac{c}{N_k^2 T_l}$.

Consider $I_{b,3}^{(kl)}$. Note that

$$\mathbb{E}_P[\psi_{it}^{(0)} \psi_{jt}^{(0)}] = \text{cov}(\psi_{it}^{(0)}, \psi_{jt}^{(0)}) = \mathbb{E}_P[\text{cov}(\psi_{it}^{(0)}, \psi_{jt}^{(0)} | \gamma_t)] + \text{cov}(\mathbb{E}_P[\psi_{it}^{(0)} | \gamma_t], \mathbb{E}_P[\psi_{jt}^{(0)} | \gamma_t]) = 0 + \mathbb{E}_P[g_t g'_t],$$

where the second equality follows from the law of total covariance. Due to identical distribution of γ_t , $\mathbb{E}_P[g_t g'_t]$ does not vary over t and so $I_{b,3}^{(kl)} = 0$.

To bound $I_{b,2}^{kl}$, we can rewrite it by triangle inequality as follows

$$\frac{1}{c} |I_{b,2}^{kl}| \leq \left| \frac{1}{T_l} \sum_{t \in S_l} I_{b,2,t}^{(kl)} \right| + \left| \frac{1}{T_l} \sum_{t \in S_l} \tilde{I}_{b,2,t}^{(kl)} \right|,$$

where

$$\begin{aligned} I_{b,2,t}^{(kl)} &:= \frac{1}{N_k^2} \sum_{i,j \in I_k} \left\{ \psi_{it}^{(0)} \psi_{jt}^{(0)} - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{jt}^{(0)} | \{\alpha_i\}_{i \in I_k}] \right\} \\ \tilde{I}_{b,2,t}^{(kl)} &:= \frac{1}{N_k^2} \sum_{i,j \in I_k} \left\{ \mathbb{E}_P[\psi_{it}^{(0)} \psi_{jt}^{(0)} | \{\alpha_i\}_{i \in I_k}] - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{jt}^{(0)}] \right\} \end{aligned}$$

Due to identical distribution of γ_t , $\tilde{I}_{b,2,t}^{(kl)}$ does not vary over t so that $\mathbb{E}_P \left[\frac{1}{T_l} \sum_{t \in S_l} \tilde{I}_{b,2,t}^{(kl)} \right]^2 = \mathbb{E}_P \left[\tilde{I}_{b,2,t}^{(kl)} \right]^2$.

Denote $\zeta_{ij,t} = \psi_{it}^{(0)} \psi_{jt}^{(0)}$. By direct calculation, we have

$$\begin{aligned} \mathbb{E}_P \left[\tilde{I}_{b,2,t}^{(kl)} \right]^2 &= \frac{1}{N_k^4} \sum_{i,j \in I_k} \sum_{i',j' \in I_k} \mathbb{E}_P \left[\left(\mathbb{E}_P[\zeta_{ij,t} | \alpha_i, \alpha_j] - \mathbb{E}_P[\zeta_{ij,t}] \right) \left(\mathbb{E}_P[\zeta_{i'j',t} | \alpha_{i'}, \alpha_{j'}] - \mathbb{E}_P[\zeta_{i'j',t}] \right) \right] \\ &\lesssim \frac{1}{N_k} \mathbb{E}_P[\zeta_{ij,t}]^2 < \frac{1}{N_k} \mathbb{E}_P \left[\psi_{it}^{(0)} \right]^4 = O(1/N_k). \end{aligned}$$

where the first inequality follows from the assumption that α_i is independent over i and an application of Hölder's inequality and Jensen's inequality. The second inequality follows from Hölder's inequality and the last equality follows from Assumption 3.5(ii) with some $p > 4$. Therefore, by Markov inequality, we have

$$\left| \frac{1}{T_l} \sum_{t \in S_l} \tilde{I}_{b,2,t}^{(kl)} \right| = O_P(N_k^{-1/2}) = O_P(N^{-1/2}).$$

Now consider $\left| \frac{1}{T_l} \sum_{t \in S_l} I_{b,2,t}^{(kl)} \right|$. Note that conditional on $\{\alpha_i\}$, $I_{b,2,t}^{(kl)}$ is also β -mixing with the mixing coefficient same as γ_l . Then, with an application of the conditional version of Theorem 14.2 from Davidson (1994), we have

$$\left(\mathbb{E}_P \left[\left| \mathbb{E}_P [I_{b,2,t}^{(kl)} | \{\alpha_i\}_{i \in I_k}, \mathcal{F}_{-\infty}^{t-l}] \right|^2 | \{\alpha_i\}_{i \in I_k} \right] \right)^{1/2} \leq 2(2^{1/2} + 1)\beta(l)^{1/2 - \frac{2}{q}} \left(\mathbb{E}_P \left[|I_{b,2,t}^{(kl)}|^{\frac{q}{2}} | \{\alpha_i\}_{i \in I_k} \right] \right)^{\frac{2}{q}}.$$

Then, we can apply the conditional version of Lemma A from Hansen (1992) to show that

$$\begin{aligned} \left(\mathbb{E}_P \left[\left| \frac{1}{T_l} \sum_{t \in S_l} I_{b,2,t}^{(kl)} \right|^2 | \{\alpha_i\}_{i \in I_k} \right] \right)^{1/2} &\lesssim \frac{1}{T_l} \sum_{l=1}^{\infty} \beta(l)^{1/2 - \frac{2}{q}} \left(\sum_{t \in S_l} \left(\mathbb{E}_P \left[|I_{b,2,t}^{(kl)}|^{\frac{q}{2}} | \{\alpha_i\}_{i \in I_k} \right] \right)^{\frac{4}{q}} \right)^{1/2} \\ &\lesssim \frac{1}{\sqrt{T_l}} \left(\mathbb{E}_P \left[|I_{b,2,t}^{(kl)}|^{\frac{q}{2}} | \{\alpha_i\}_{i \in I_k} \right] \right)^{\frac{2}{q}} \end{aligned}$$

By conditional Markov inequality, we have

$$\mathbb{P} \left(\left| \frac{1}{T_l} \sum_{t \in S_l} I_{b,2,t}^{(kl)} \right| > \varepsilon | \{\alpha_i\}_{i \in I_k} \right) = O \left(T_l^{-1} \mathbb{E}_P \left[|I_{b,2,t}^{(kl)}|^{\frac{q}{2}} | \{\alpha_i\}_{i \in I_k} \right] \right)$$

By Minkowski's inequality for infinite sums, Jensen's inequality, and Hölder's inequality, we have

$$\begin{aligned} \left(\mathbb{E}_P \left[|I_{b,2,t}^{(kl)}|^{\frac{q}{2}} \right] \right)^{\frac{2}{q}} &\lesssim \frac{1}{N_k^2} \sum_{i,j \in I_k} \left(\mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{jt}^{(0)} \right]^{\frac{q}{2}} \right)^{\frac{2}{q}} \\ &\leq \frac{1}{N_k^2} \sum_{i,j \in I_k} \left(\mathbb{E}_P \left[\psi_{it}^{(0)q} \right] \right)^{\frac{2}{q}} \leq a_1^2, \end{aligned}$$

where the last inequality follows from Assumption 3.5(ii). Then, by the law of iterated expectation, we have

$$\mathbb{P} \left(\left| \frac{1}{T_l} \sum_{t \in S_l} I_{b,2,t}^{(kl)} \right| > \varepsilon \right) = O \left(T_l^{-1/2} \right).$$

Therefore, we have shown $|I_{b,2}^{kl}| = O_P(N_k^{-1}) + O_P(T_l^{-1/2}) = O_P(T^{-1/2})$.

The argument to bound $I_{b,1}^{kl}$ is similar to the that for $I_{a,1}^{kl}$. By the similar inequality for $|I_{a,1}^{kl}|$, we have

$$\frac{1}{c} |I_{b,1}^{kl}| \lesssim R_{kl} \left\{ \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 \right)^{1/2} + R_{kl} \right\},$$

where

$$R_{kl} = \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right)^2 \right)^{1/2}.$$

We have shown in the proof of Claim C.4 that $\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 = O_P(1)$ and $R_{kl} = O_P(N^{-1} + (r'_{NT})^2)$. So $|I_{b,1}^{kl}| = O_P(N^{-1/2} + r'_{NT})$. To summarize

$$\left| \hat{\Omega}_{b,kl} - cE_P[g_t g'_t] \right| = O_P(N^{-1/2}) + O_P(T^{-1/2}) + O_P(N^{-1/2} + r'_{NT}) = O_P(N^{-1/2} + r'_{NT}),$$

which completes the proof of Claim C.5.

Proof of Claim C.6. By triangle inequality, we have

$$\left| \hat{\Omega}_{c,kl} \right| \leq \left| I_{c,1}^{(kl)} \right| + \left| I_{c,2}^{(kl)} \right| + \left| I_{c,3}^{(kl)} \right|$$

where

$$\begin{aligned} I_{c,1}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l} \left\{ \hat{\psi}_{it}^{(kl)} \hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \psi_{it}^{(0)} \right\}, \\ I_{c,2}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l} \left\{ \psi_{it}^{(0)} \psi_{it}^{(0)} - E_P[\psi_{it}^{(0)} \psi_{it}^{(0)}] \right\}, \\ I_{c,3}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l} E_P[\psi_{it}^{(0)} \psi_{it}^{(0)}], \end{aligned}$$

Consider $I_{c,3}^{(kl)}$. Note that under Assumption DML2(i), we have

$$E_P[\psi_{it}^{(0)} \psi_{it}^{(0)}] \leq a_1^2.$$

Thus, $I_{c,3}^{(kl)} = O_P(1/T_l) = O_P(T^{-1})$.

To bound $I_{c,2}^{kl}$, consider the variance of $I_{c,2}^{kl}$. Denote $\xi_{it} = \psi_{it}^{(0)} \psi_{it}^{(0)} - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{it}^{(0)}]$.

$$\begin{aligned}
\text{Var} \left(I_{c,2}^{kl} \right) &= \left(\frac{K/L}{N_k T_l^2} \right)^2 \mathbb{E}_P \left[\sum_{i \in I_k, t \in S_l} \xi_{it} \right]^2 \\
&= \left(\frac{K/L}{N_k T_l^2} \right)^2 \left\{ \sum_{i \in I_k, t \in S_l, r \in S_l} \mathbb{E}_P [\xi_{it} \xi_{is}] + \sum_{t \in S_l, i \in I_k, j \in I_k} \mathbb{E}_P [\xi_{it} \xi_{jt}] - \sum_{t \in S_l, i \in I_k} \mathbb{E}_P [\xi_{it} \xi_{it}] \right. \\
&\quad \left. + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k} \mathbb{E}_P [\xi_{it} \xi_{j,t+m}] - 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i \in I_k} \mathbb{E}_P [\xi_{it} \xi_{i,t+m}] \right\} \\
&\leq \left(\frac{K/L}{N_k T_l^2} \right)^2 \left\{ \sum_{i \in I_k, t \in S_l, r \in S_l} \mathbb{E}_P |\xi_{it} \xi_{is}| + \sum_{t \in S_l, i \in I_k, j \in I_k} \mathbb{E}_P |\xi_{it} \xi_{jt}| + \sum_{t \in S_l, i \in I_k} \mathbb{E}_P |\xi_{it} \xi_{it}| \right. \\
&\quad \left. + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k} \mathbb{E}_P |\xi_{it} \xi_{j,t+m}| + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i \in I_k} \mathbb{E}_P |\xi_{it} \xi_{i,t+m}| \right\} \\
&\leq \left(\frac{K/L}{N_k T_l^2} \right)^2 \left\{ \sum_{i \in I_k, t \in S_l, r \in S_l} \mathbb{E}_P |\xi_{it}|^2 + \sum_{t \in S_l, i \in I_k, j \in I_k} \mathbb{E}_P |\xi_{it}|^2 + \sum_{t \in S_l, i \in I_k} \mathbb{E}_P |\xi_{it}|^2 \right. \\
&\quad \left. + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i,j \in I_k} \mathbb{E}_P |\xi_{it}|^2 + 2 \sum_{m=1}^{T_l-1} \sum_{t=\min(S_l)}^{\max(S_l)-m} \sum_{i \in I_k} \mathbb{E}_P |\xi_{it}|^2 \right\}.
\end{aligned}$$

where the last inequality follows from Hölder's inequality. Note that for each i, t , by Hölder's inequality and Assumption DML2(i), we have

$$\mathbb{E}_P |\xi_{it}|^2 \lesssim \mathbb{E}_P [\psi(W_{it}; \theta_0, \eta_0)^4] \leq a_1^4.$$

Thus, $\text{Var} \left(I_{c,2}^{kl} \right) = O(T^{-2})$ and so $I_{c,2}^{kl} = O_P(T^{-1})$.

Now consider $I_{c,1}^{(kl)}$. Following the same steps for $I_{b,1}^{(kl)}$, we have

$$\begin{aligned}
|I_{c,1}^{kl}| &\leq \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l} |\hat{\psi}_{it}^{(kl)} \hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \psi_{it}^{(0)}| \\
&\leq \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l} \left\{ |\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)}|^2 + 2 |\psi_{it}^{(0)}| |\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)}| \right\} \\
&\lesssim \frac{K/L}{T_l} R_{kl} \left\{ \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} (\psi_{it}^{(0)})^2 \right)^{1/2} + R_{kl} \right\},
\end{aligned}$$

where

$$R_{kl} = \left(\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\hat{\psi}_{it}^{(kl)} - \psi_{it}^{(0)} \right)^2 \right)^{1/2}.$$

We have shown in the proof of Claim C.4 that $\frac{1}{N_k T_l} \sum_{i \in I_k, t \in S_l} \left(\psi_{it}^{(0)} \right)^2 = O_P(1)$ and $R_{kl} = O_P \left(N^{-1} + (r'_{NT})^2 \right)$. So, $\left| I_{c,1}^{kl} \right| = O_P \left((NT)^{-1} + (r'_{NT})^2/T \right)$. To summarize

$$\left| \hat{\Omega}_{c,kl} \right| = O_P \left(T^{-1} \right) + O_P \left((NT)^{-1} + (r'_{NT})^2/T \right) = O_P \left(T^{-1} \right),$$

which completes the proof of Claim C.6.

Proof of Claim C.7. By triangle inequality, we have

$$\left| \hat{\Omega}_{d,kl} - c \sum_{m=1}^{\infty} E_P [g_t g'_{t+m}] \right| \leq \left| I_{d,1}^{(kl)} \right| + \left| I_{d,2}^{(kl)} \right| + \left| I_{d,3}^{(kl)} \right| + \left| I_{d,4}^{(kl)} \right| + \left| I_{d,5}^{(kl)} \right| + \left| I_{d,6}^{(kl)} \right|$$

where

$$\begin{aligned} I_{d,1}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} \left\{ \hat{\psi}_{it}^{(kl)} \hat{\psi}_{j,t+m}^{(kl)} - \psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right\}, \\ I_{d,2}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} \left\{ \psi_{it}^{(0)} \psi_{j,t+m}^{(0)} - E_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] \right\}, \\ I_{d,3}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} \left(k \left(\frac{m}{M} \right) - 1 \right) \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} E_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right], \\ I_{d,4}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{m=M}^{\infty} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} E_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right], \\ I_{d,5}^{(kl)} &:= \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} E_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] - c \sum_{m=1}^{\infty} E_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right], \\ I_{d,6}^{(kl)} &:= c \sum_{m=1}^{\infty} E_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] - c \sum_{m=1}^{\infty} E_P \left[g_t g_{t+m} \right] \end{aligned}$$

and $\frac{K/L}{N_k T_l^2} = \frac{c}{N_k^2 T_l}$.

Consider $I_{d,6}^{(kl)}$. By the law of total covariance, we have

$$\begin{aligned} \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] &= \text{cov}(\psi_{it}^{(0)}, \psi_{j,t+m}^{(0)}) \\ &= \mathbb{E}_P[\text{cov}(\psi_{it}^{(0)}, \psi_{j,t+m}^{(0)} | \gamma_t, \gamma_{t+m})] + \text{cov}(\mathbb{E}_P[\psi_{it}^{(0)} | \gamma_t], \mathbb{E}_P[\psi_{j,t+m}^{(0)} | \gamma_{t+m}]) \\ &= 0 + \mathbb{E}_P[g_t g_{t+m}'], \end{aligned}$$

where the last equality follows from the component representation and its properties (iii) and (iv) shown in the proof of Claim C.3. Therefore, $I_{d,6}^{(kl)} = 0$.

Consider $I_{d,5}^{(kl)}$. The strict stationarity of γ_t implies that $\psi_{it}^{(0)}$ is also strictly stationary over t . And under Assumption 2, there is no heterogeneity across i . Then, as $M, T \rightarrow \infty$, we have $I_{d,5}^{(kl)} = o(1)$.

Consider $I_{d,4}^{(kl)}$. Under Assumption DML2(i), $\left(\mathbb{E}_P[\psi_{it}^{(0)} | \gamma_t] \right)^{1/q} \leq a_1$ for $p > 4$. And conditional on α_i , $\psi_{it}^{(0)}$ is β -mixing with the mixing coefficient not larger than that of γ_t . Then by Theorem 14.13(ii) in Hansen (2022), we have

$$\left| \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} | \{\alpha_i\}_{i \in I_k} \right] \right| \leq 8 \left(\mathbb{E}_P \left[|\psi_{it}^{(0)}|^q | \alpha_i \right] \right)^{1/q} \left(\mathbb{E}_P \left[|\psi_{j,t+m}^{(0)}|^q | \alpha_j \right] \right)^{1/q} \alpha_\gamma(m)^{1-2/q}$$

By iterated expectation and Jensen's inequality, we have

$$\begin{aligned} \left| \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] \right| &\leq \mathbb{E}_P \left[\left| \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} | \{\alpha_i\}_{i \in I_k} \right] \right| \right] \\ &\leq 8 \mathbb{E}_P \left[\left(\mathbb{E}_P \left[|\psi_{it}^{(0)}|^q | \alpha_i \right] \right)^{1/q} \left(\mathbb{E}_P \left[|\psi_{j,t+m}^{(0)}|^q | \alpha_j \right] \right)^{1/q} \alpha_\gamma(m)^{1-2/q} \right] \\ &\leq 8 \mathbb{E}_P \left[\left(\mathbb{E}_P \left[|\psi_{it}^{(0)}|^q | \alpha_i \right] \right)^{1/q} \right] \mathbb{E}_P \left[\left(\mathbb{E}_P \left[|\psi_{j,t+m}^{(0)}|^q | \alpha_j \right] \right)^{1/q} \right] \alpha_\gamma(m)^{1-2/q} \\ &\lesssim a_1^2 \alpha_\gamma(m)^{1-2/q} \end{aligned}$$

where the third inequality follows from that α_i are independent over i . Then, as $M \rightarrow \infty$,

$$\begin{aligned} \left| I_{d,4}^{(kl)} \right| &\leq \frac{K/L}{N_k T_l^2} \sum_{m=M}^{\infty} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} \left| \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] \right| \lesssim \sum_{m=M}^{\infty} \alpha_\gamma(m)^{1-2/q} \leq \sum_{m=M}^{\infty} \beta_\gamma(m)^{1-2/q} \\ &\leq c_\kappa \sum_{m=M}^{\infty} \exp(-\kappa m) = c_\kappa \left(\frac{1}{1 - e^{-\kappa}} - \frac{1 - e^{-\kappa M}}{1 - e^{-\kappa}} \right) = O(e^{-\kappa M}). \end{aligned}$$

Consider $I_{d,3}^{(kl)}$.

$$\begin{aligned} |I_{d,3}^{(kl)}| &\leq \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} \left| k \left(\frac{m}{M} \right) - 1 \right| \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} \left| \mathbb{E}_P \left[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right] \right| \\ &\leq c a_1^2 \sum_{m=1}^{M-1} \left| k \left(\frac{m}{M} \right) - 1 \right| \alpha_\gamma(m)^{1-2/q}. \end{aligned}$$

Note that for each m , $\left| k \left(\frac{m}{M} \right) - 1 \right| \rightarrow 0$ as $M \rightarrow \infty$. Since $\left| k \left(\frac{m}{M} \right) - 1 \right| \alpha_\gamma(m)^{1-2/q} \leq 1$, we can apply dominated convergence theorem to conclude that $I_{d,3}^{(kl)} = o(1)$.

To bound $I_{d,2}^{kl}$, we can rewrite it by triangle inequality as follows

$$\frac{1}{c} |I_{d,2}^{kl}| \leq \left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} I_{d,2,tm}^{(kl)} \right| + \left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \tilde{I}_{d,2,tm}^{(kl)} \right|,$$

where

$$\begin{aligned} I_{d,2,tm}^{(kl)} &:= \frac{1}{N_k^2} \sum_{i,j \in I_k, i \neq j} \left\{ \psi_{it}^{(0)} \psi_{j,t+m}^{(0)} - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} | \{\alpha_i\}_{i \in I_k}] \right\} \\ \tilde{I}_{d,2,tm}^{(kl)} &:= \frac{1}{N_k^2} \sum_{i,j \in I_k, i \neq j} \left\{ \mathbb{E}_P[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)} | \{\alpha_i\}_{i \in I_k}] - \mathbb{E}_P[\psi_{it}^{(0)} \psi_{j,t+m}^{(0)}] \right\} \end{aligned}$$

Due to identical distribution of γ_t , $\tilde{I}_{d,2,tm}^{(kl)}$ does not vary over t so that $\mathbb{E}_P \left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \tilde{I}_{d,2,tm}^{(kl)} \right|^2 \leq \mathbb{E}_P \left| \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \tilde{I}_{d,2,tm}^{(kl)} \right|^2$. And by Minkowski's inequality, we have

$$\left(\mathbb{E}_P \left| \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \tilde{I}_{d,2,tm}^{(kl)} \right|^2 \right)^{1/2} \leq \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \left(\mathbb{E}_P \left[\tilde{I}_{d,2,tm}^{(kl)} \right]^2 \right)^{1/2}$$

Denote $\zeta_{ijm} = \psi_{it}^{(0)} \psi_{j,t+m}^{(0)}$. By direct calculation, we have

$$\begin{aligned} \mathbb{E}_P \left| \tilde{I}_{d,2,tm}^{(kl)} \right|^2 &= \frac{1}{N_k^4} \sum_{i,j \in I_k} \sum_{i',j' \in I_k} \mathbb{E}_P \left[(\mathbb{E}_P[\zeta_{ijm} | \alpha_i, \alpha_j] - \mathbb{E}_P[\zeta_{ij,t}]) (\mathbb{E}_P[\zeta_{i'j'} | \alpha_{i'}, \alpha_{j'}] - \mathbb{E}_P[\zeta_{i'j'}]) \right] \\ &\lesssim \frac{1}{N_k} \mathbb{E}_P[\zeta_{ijm}]^2 < \frac{1}{N_k} \mathbb{E}_P \left[\psi_{it}^{(0)} \right]^4 = O(1/N_k). \end{aligned}$$

where the first inequality follows from the assumption that α_i is independent over i and an application of Hölder's inequality and Jensen's inequality. The second inequality follows from Hölder's inequality and the

last equality follows from Assumption 3.5(ii) with some $p > 4$. Therefore, we have $\left(\mathbb{E}_P \left| \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \tilde{I}_{d,2,tm}^{(kl)} \right|^2 \right)^{1/2} \leq O_P \left(\frac{M}{N^{1/2}} \right) = O_P \left(\frac{M}{T^{1/2}} \right)$. By Markov inequality, we have $\left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \tilde{I}_{d,2,tm}^{(kl)} \right| = O_P \left(\frac{M}{T^{1/2}} \right)$.

Now consider $\left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} I_{d,2,tm}^{(kl)} \right|$. By Minkowski's inequality, we have

$$\left(\mathbb{E}_P \left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} I_{d,2,tm}^{(kl)} \right|^2 \right)^{1/2} \leq \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \left(\mathbb{E}_P \left| \frac{1}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} I_{d,2,tm}^{(kl)} \right|^2 \right)^{1/2}$$

Following the same steps as for $I_{b,2,tm}^{(kl)}$, we can show

$$\mathbb{E}_P \left| \frac{1}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} I_{d,2,tm}^{(kl)} \right|^2 = O(T_l^{-1}).$$

Therefore, $\left| \sum_{m=1}^{M-1} \frac{k \left(\frac{m}{M} \right)}{T_l} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} I_{d,2,tm}^{(kl)} \right| = O_P \left(\frac{M}{T_l^{1/2}} \right) = O_P \left(\frac{M}{T^{-1/2}} \right)$. We have shown $|I_{b,2}^{kl}| = O_P(1/N_k) + O_P \left(\frac{M}{T^{-1/2}} \right) = O_P \left(\frac{M}{T^{-1/2}} \right)$.

Consider $I_{d,1}^{kl}$. Denote

$$I_{d,1,m}^{(kl)} = \frac{K/L}{N_k T_l^2} \sum_{t=\lfloor S_l \rfloor}^{\lceil S_l \rceil - m} \sum_{i \in I_k, j \in I_k, j \neq i} \left\{ \hat{\psi}_{it}^{(kl)} \hat{\psi}_{j,t+m}^{(kl)} - \psi_{it}^{(0)} \psi_{j,t+m}^{(0)} \right\},$$

for each m . Then, $I_{d,1}^{(kl)} = \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) I_{d,1,m}^{(kl)}$. Following the same steps as for $I_{a,1}^{kl}$, we can show

$$|I_{d,1,m}^{kl}| = O_P(T^{-1/2} + r'_{NT}),$$

for each m . Therefore, $|I_{d,1}^{kl}| = O_P \left(\frac{M}{T^{-1/2}} + M r'_{NT} \right)$. Note that $M r'_{NT} \leq M \delta_{NT} N^{-1/2} = \frac{M}{T^{1/2}} \frac{T^{1/2}}{N^{1/2}} \delta_{NT} = o(1)$.

To summarize

$$\begin{aligned} \left| \hat{\Omega}_{d,kl} - c \sum_{m=1}^{\infty} \mathbb{E}_P[g_t g'_t] \right| &= O_P \left(\frac{M}{T^{-1/2}} + M r'_{NT} \right) + O_P \left(\frac{M}{T^{1/2}} \right) + o(1) + O(e^{-\kappa M}) + o(1) + 0 \\ &= o_P(1). \end{aligned}$$

which completes the proof of Claim C.7.

□

Proof of Theorem 3.3. Since (K, L) are fixed constants, it suffices to show for each (k, l) that $\hat{\Omega}_{\text{NW},kl} := \frac{K/L}{N_k T_l^2} \sum_{i \in I_k, t \in S_l, r \in S_l} k \left(\frac{|t-r|}{M} \right) \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{ir}; \hat{\theta}, \hat{\eta}_{kl})' = o_P(1)$. Note that we can rewrite $\hat{\Omega}_{\text{NW},kl}$ as

$$\hat{\Omega}_{\text{NW},kl} = \hat{\Omega}_{c,kl} + \hat{\Omega}_{e,kl} - \hat{\Omega}_{d,kl}$$

where $\hat{\Omega}_{c,kl}$ and $\hat{\Omega}_{d,kl}$ are defined in the beginning of the proof of Theorem 3.2, and $\hat{\Omega}_{e,kl}$ is defined as follows:

$$\hat{\Omega}_{e,kl} := \frac{K/L}{N_k T_l^2} \sum_{m=1}^{M-1} k \left(\frac{m}{M} \right) \sum_{t=[S_l]}^{[S_l]-m} \sum_{i \in I_k, j \in I_k} \psi(W_{it}; \hat{\theta}, \hat{\eta}_{kl}) \psi(W_{j,t+m}; \hat{\theta}, \hat{\eta}_{kl})'.$$

Observe that by replacing $\hat{\Omega}_{d,kl}$ by $\hat{\Omega}_{e,kl}$, each step in the proof of Claim C.7 also follows. It implies that $\hat{\Omega}_{e,kl} = \hat{\Omega}_{d,kl} + o_P(1)$. By Lemma A.6, we have $\hat{\Omega}_{c,kl} = O_P(T^{-1})$. Therefore, we conclude that $\hat{\Omega}_{\text{NW},kl} = o_P(1)$.

□

Appendix D

Proof of Corollary 4.1. Corollary 4.1 follows from an application of Theorem 3.1. Since Assumptions AHK, AR, and ND are directly imposed, it suffices to verify Assumptions DML1, DML2 where the high-level assumptions on the rates will be verified by applying Theorem 2.

Let the nuisance realization set \mathcal{T}_{NT} be the set of all $\eta = (\zeta', \pi', \beta')'$ such that $\|f'_{it}(\zeta - \zeta_0)\|_{P,2} = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right)$, $\|f'_{it}(\pi - \pi_0)\|_{P,2} = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right)$, and $\|f'_{it}(\beta - \beta_0)\|_{P,2} = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right)$. Therefore, \mathcal{T}_{NT} contains η_0 . Under the approximately sparsity condition and Assumption GMD, $\hat{\eta}_{k,l}$ are obtained for each $k = 1, \dots, K$ and $l = 1, \dots, L$. Note that every first-stage estimation uses the auxiliary samples instead of the full sample so the empirical norms are in terms of different samples for each (k, l) . However, I will suppress its dependence on (k, l) with the slightly abused notation: I will use N for N_{-k} , T for T_{-l} , and I will use the index set $\{(i, t) : i = 1, \dots, N; t = 1, \dots, T\}$ instead of $\mathcal{W}(-k, -l)$ to denote the auxiliary sample.

To show $\hat{\beta} \in \mathcal{T}_{NT}$ with probability approaching one, we need to show $\|f'_{it}(\hat{\beta} - \beta_0)\|_{P,2} = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right) =: O(\rho_{NT})$. Under Assumptions AHK, AR, SE, and REG-P(i)-(v), we can apply Theorem 2 to obtain $\|f'_{it}(\hat{\beta} - \beta_0)\|_{NT,2} = O_P(\rho_{NT})$, i.e. $\frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \left[f'_{it}(\hat{\beta} - \beta_0) \right]^2 = O_P(\rho_{NT}^2)$. That is to say, for any $\epsilon > 0$, there exists C_ϵ such that

$$P\left(\frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \left[f'_{it}(\hat{\beta} - \beta_0) \right]^2 > C_\epsilon \rho_{NT}^2\right) < \epsilon.$$

Denote $F_{NT} = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T \left[f'_{it}(\hat{\beta} - \beta_0) \right]^2$. Consider the following decomposition:

$$\mathbb{E} [F_{NT}] = \mathbb{E} [F_{NT} 1\{F_{NT} \leq C_\epsilon \rho_{NT}^2\}] + \mathbb{E} [F_{NT} 1\{F_{NT} > C_\epsilon \rho_{NT}^2\}] \leq C_\epsilon \rho_{NT}^2 + \mathbb{E} [F_{NT} 1\{F_{NT} > C_\epsilon \rho_{NT}^2\}].$$

By Holder's inequality, we have, for some $\delta > 0$,

$$\mathbb{E} [F_{NT} 1\{F_{NT} > C_\epsilon \rho_{NT}^2\}] \leq \mathbb{E} [F_{NT}]^{1+\delta} \mathbb{E} [1\{F_{NT} > C_\epsilon \rho_{NT}^2\}] \leq \mathbb{E} [F_{NT}]^{1+\delta} \epsilon.$$

Furthermore, by Minkowski's inequality, we have

$$\left(\mathbb{E} [F_{NT}]^{1+\delta} \right)^{\frac{1}{1+\delta}} \leq \left(\mathbb{E} \left[f'_{it}(\hat{\beta} - \beta_0) \right]^{2(1+\delta)} \right)^{\frac{1}{1+\delta}} \leq \left(\left(\mathbb{E} \left[f'_{it}\hat{\beta} \right]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} + \left(\mathbb{E} [f'_{it}\beta_0]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} \right)^2.$$

Theorem 2 also gives that $\|\hat{\beta} - \beta_0\|_2 \rightarrow o_P(1)$, given $s = xxx$ and $\gamma = xxx$. So, there exists a sequence $\delta_{NT} = o(1)$ such that $\|\hat{\beta} - \beta_0\|_2 \leq \delta_{NT}$ with probability approaching one. Then, we have

$$\left| f'_{it}\hat{\beta} \right| \leq \sup_{\|\beta - \beta_0\|_2 \leq \delta_{NT}} |f'_{it}\beta| \leq |f'_{it}\beta_0| + \sup_{\|\beta - \beta_0\|_2 \leq \delta_{NT}} |f'_{it}(\beta - \beta_0)| \leq 2 |f'_{it}\beta_0|.$$

Therefore, we have

$$\left(\mathbb{E} [F_{NT}]^{1+\delta} \right)^{\frac{1}{1+\delta}} \leq \left(3 \left(\mathbb{E} [f'_{it}\beta_0]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} \right)^2.$$

Observing that $f'_{it}\beta_0 = Y_{it} - r_{it}^Y - V_{it}^Y$, Minkowski's inequality and Assumption REG-P(iv) imply that

$$\left(\mathbb{E} [f'_{it}\beta_0]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} \leq \left(\mathbb{E} [Y_{it}]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} + \left(\mathbb{E} [r_{it}^Y]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} + \left(\mathbb{E} [V_{it}^Y]^{2(1+\delta)} \right)^{\frac{1}{2(1+\delta)}} < \infty$$

Similarly, we can show $\left(\mathbb{E} [f'_{it}\beta_0]^{4(1+\delta)} \right)^{\frac{1}{4(1+\delta)}} \leq \infty$ and $\left(\mathbb{E} [f'_{it}\pi_0]^{4(1+\delta)} \right)^{\frac{1}{4(1+\delta)}} \leq \infty$, which will be used later.

Putting together, we have

$$\mathbb{E} [F_{NT}] \leq C_\epsilon \rho_{NT}^2 + O(\epsilon)$$

By taking ϵ sufficiently small, we have $\mathbb{E} [F_{NT}] = c$, which in turn gives $\mathbb{E} \left[f'_{it}(\hat{\beta} - \beta_0) \right]^2 = O(\rho_{NT}^2)$ and $\left\| f'_{it}(\hat{\beta} - \beta_0) \right\|_{P,2} = O(\rho_{NT})$. Similarly, we have $\left\| f'_{it}(\hat{\pi} - \pi_0) \right\|_{P,2} = O(\rho_{NT})$ and $\left\| f'_{it}(\hat{\xi} - \xi_0) \right\|_{P,2} = O(\rho_{NT})$.

Next, we will show $E [r_{it}^Y]^2 = O\left(\frac{s}{N \wedge T}\right)$ and $E [r_{it}^D]^2 = O\left(\frac{s}{N \wedge T}\right)$. It is given by the sparse approximation condition that $\|r_{it}\|_{NT,2}^2 = O_P\left(\frac{s}{N \wedge T}\right)$. So, for any $\epsilon > 0$, there exists $C_\epsilon < \infty$ such that

$$P\left(\frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T [r_{it}]^2 > C_\epsilon \rho_{NT}^2\right) < \epsilon.$$

Denote $R_{NT} = \frac{1}{NT} \sum_{i=1}^N \sum_{t=1}^T [r_{it}]^2$. Using the same trick, we consider the following decomposition:

$$\begin{aligned} E [R_{NT}] &= E [R_{NT} 1\{R_{NT} \leq C_\epsilon \rho_{NT}^2\}] + E [R_{NT} 1\{R_{NT} > C_\epsilon \rho_{NT}^2\}] \leq C_\epsilon \frac{s}{N \wedge T} + E [R_{NT} 1\{R_{NT} > C_\epsilon \rho_{NT}^2\}] \\ &\leq C_\epsilon \frac{s}{N \wedge T} + \left(E [R_{NT}]^{1+\delta}\right)^{\frac{1}{1+\delta}} \epsilon \end{aligned}$$

where the last line follows from Holder's inequality with some $\delta > 0$. By Minkowski's inequality, we have

$$\left(E [R_{NT}]^{1+\delta}\right)^{\frac{1}{1+\delta}} \leq \left(E [r_{it}^Y]^{2(1+\delta)}\right)^{\frac{1}{1+\delta}} < \infty.$$

Therefore, by taking ϵ sufficiently small, we have $E [r_{it}^Y]^2 = E [R_{NT}] = O\left(\frac{s}{N \wedge T}\right)$. Similarly, we have $E [r_{it}^D]^2$.

From this step, we start verifying Assumptions DML1 and DML2. Assumption DML1(i) (linear orthogonal score) is satisfied with

$$\begin{aligned} \psi^a(W_{it}; \eta) &= -(Z_{it} - f'_{it}\zeta)(D_{it} - f'_{it}\pi), \\ \psi^b(W_{it}; \eta) &= (Z_{it} - f'_{it}\zeta)(Y_{it} - f'_{it}\beta) \end{aligned}$$

Consider Assumption DML1(ii) (near-Neyman orthogonality). By sparse approximation condition, we

have $\frac{1}{NT} \sum r_{it} \leq \|r_{it}\|_{NT,2} = O_P\left(\sqrt{\frac{s}{N \vee T}}\right)$

$$\begin{aligned}
& \sup_{\eta \in \mathcal{T}_{NT}} \left\| \partial_r E \left[\psi(W_{it}; \theta_0, \eta_0 + r(\eta - \eta_0)) \right] \Big|_{r=0} \right\|_2 \\
&= \sup_{\eta \in \mathcal{T}_{NT}} \left| E \left[f'_{it}(\zeta - \zeta_0)(Y_{it} - f'_{it}\beta_0 - (D_{it} - f'_{it}\pi_0)\theta_0) + (Z_{it} - f'_{it}\zeta_0)(-f'_{it}(\beta - \beta_0) + f'_{it}(\pi - \pi_0)\theta_0) \right] \right| \\
&= \sup_{\eta \in \mathcal{T}_{NT}} \left| E \left[f'_{it}(\zeta - \zeta_0)(r_{it}^Y + V_{it}^Y - (r_{it}^D + V_{it}^D)\theta_0) + (V_{it}^Z)(-f'_{it}(\beta - \beta_0) + f'_{it}(\pi - \pi_0)\theta_0) \right] \right| \\
&= \sup_{\eta \in \mathcal{T}_{NT}} \left| E \left[f'_{it}(\zeta - \zeta_0)(r_{it}^Y - r_{it}^D\theta_0) \right] \right| \text{ by the exogeneity conditions} \\
&\leq \sup_{\eta \in \mathcal{T}_{NT}} \|f'_{it}(\zeta - \zeta_0)\|_{P,2} (\|r_{it}^Y\|_{P,2} + \|r_{it}^D\theta_0\|_{P,2}) \text{ by Jensen's, Hölder's, and Minkowski's inequalities} \\
&= O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right) O\left(\sqrt{\frac{s}{N \wedge T}}\right) = O\left(\frac{s}{N \wedge T} \sqrt{\log(p/\gamma)}\right).
\end{aligned}$$

By taking $s = o\left(\sqrt{\frac{N}{\log(p/\gamma)}}\right)$, Assumption DML1(ii) is satisfied.

Assumption DML1(iii) (twice-Gateaux differentiability) is verified by checking $\partial_r^2 E \left[\psi(W_{it}; \theta_0, \eta_0 + r(\eta - \eta_0)) \right]$ directly. Assumption DML1(iv) (non-singularity) is implied by Assumption REG-P(v).

Consider Assumption DML2(i):

$$\begin{aligned}
m_{NT} &= \sup_{\eta \in \mathcal{T}_{NT}} \left(E \left\| (Z_{it} - f'_{it}\zeta)(Y_{it} - f'_{it}\beta - (D_{it} - f'_{it}\pi)\theta) \right\|^q \right)^{1/q} \\
&= \sup_{\eta \in \mathcal{T}_{NT}} \left(E \left\| (f'_{it}(\zeta_0 - \zeta) + V_{it}^Z)(f'_{it}(\beta_0 - \beta) + r_{it}^Y + V_{it}^Y - (f'_{it}(\pi_0 - \pi) + r_{it}^D + V_{it}^D)\theta_0) \right\|^q \right)^{1/q} \\
m'_{NT} &= \sup_{\eta \in \mathcal{T}_{NT}} \left(E \left\| (Z_{it} - f'_{it}\zeta)(D_{it} - f'_{it}\pi) \right\|^q \right)^{1/q} \\
&= \sup_{\eta \in \mathcal{T}_{NT}} \left(E \left\| (f'_{it}(\zeta_0 - \zeta) + V_{it}^Z)(f'_{it}(\pi_0 - \pi) + r_{it}^D + V_{it}^D) \right\|^q \right)^{1/q}
\end{aligned}$$

Using Holder's inequality, Assumption REG-P(iv), and the fact that $\|\eta_0 - \eta\| = o(1)$ for $\eta \in \mathcal{T}_{NT}$, it can be verified that DML2(i) holds with $q = 2(1 + \delta)$.

Consider Assumption DML2(ii) - r_{NT} :

$$\begin{aligned}
r_{NT} &= \sup_{\eta \in \mathcal{T}_{NT}} \left\| E \left[f'_{it}(\zeta - \zeta_0)(f'_{it}(\pi_0 - \pi) + r_{it}^D + V_{it}^D) - V_{it}^Z f'_{it}(\pi_0 - \pi) \right] \right\| \\
&\leq \sup_{\eta \in \mathcal{T}_{NT}} \|f'_{it}(\zeta - \zeta_0)\|_{P,2} (\|f'_{it}(\pi_0 - \pi)\|_{P,2} + \|r_{it}^D\|_{P,2}) = O\left(\frac{s \log(p/\gamma)}{N \wedge T}\right) + O\left(\frac{s \sqrt{\log(p/\gamma)}}{N \wedge T}\right) = O\left(\frac{s \log(p/\gamma)}{N \wedge T}\right).
\end{aligned}$$

Consider Assumption DML2(ii) - r'_{NT} . Since $E[f'_{it}(\beta_0 - \hat{\beta})]^2 \rightarrow 0$ as we have shown above, we have $P(|f'_{it}(\beta_0 - \beta)| > C) \rightarrow 0$ for any constant $C > 0$. Further, we can decompose and bound it as follows:

$|f'_{it}(\beta_0 - \beta)| \leq C + |f'_{it}(\beta_0 - \beta)|1\{|f'_{it}(\beta_0 - \beta)| > C\}$. Let $\eta \in \mathcal{T}_{NT}$ and consider the following:

$$\begin{aligned} & \left(E \left\| f'_{it}(\zeta - \zeta_0)(f'_{it}(\beta_0 - \beta) + r_{it}^Y + V_{it}^Y) \right\|^2 \right)^{1/2} \\ & \leq C \|f'_{it}(\zeta - \zeta_0)\|_{P,2} + O(\|f'_{it}(\zeta - \zeta_0)\|_{P,2}) + O(\|f'_{it}(\zeta - \zeta_0)\|_{P,2} + \|f'_{it}(\zeta - \zeta_0)\|_{P,4(1+\delta)} \|f'_{it}(\zeta - \zeta_0)\|_{P,4(1+\delta)}) o(1) \\ & = O(\|f'_{it}(\zeta - \zeta_0)\|_{P,2}) + o(1) = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right) + o(1), \end{aligned}$$

where the first line follows from Holder's inequality, Assumption REG-P(vii), and $P(|f'_{it}(\beta_0 - \beta)| > C) \rightarrow 0$; the equality follows from the results shown above. Similarly, we can show

$$\left(E \left\| f'_{it}(\zeta - \zeta_0)((f'_{it}(\pi_0 - \pi) + r_{it}^D + V_{it}^D)\theta_0) + V_{it}^Z(f'_{it}(\beta - \beta_0) - f'_{it}(\pi_0 - \pi)\theta_0) \right\|^2 \right)^{1/2} = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right) + o(1)$$

Therefore, we have

$$r'_{NT} = \sup_{\eta \in \mathcal{T}_{NT}} \left\| f'_{it}(\zeta - \zeta_0)(f'_{it}(\beta_0 - \beta) + r_{it}^Y + V_{it}^Y) - V_{it}^Z(f'_{it}(\beta - \beta_0) - f'_{it}(\pi_0 - \pi)\theta_0) \right\|_{P,2} = O\left(\sqrt{\frac{s \log(p/\gamma)}{N \wedge T}}\right) + o(1)$$

By taking $s = o\left(\frac{N \wedge T}{\log(p/\gamma)}\right)$, the rate requirement for r'_{NT} in Assumption DML2(ii) is satisfied.

Consider Assumption DML2(ii) - λ'_{NT} :

$$\begin{aligned} \lambda'_{NT} &= \sup_{\eta \in \mathcal{T}_{NT}} 2 \left\| E \left[f'_{it}(\zeta_0 - \zeta)(f'_{it}(\beta_0 - \beta) - f'_{it}(\pi_0 - \pi)\theta_0) \right] \right\| \\ &\leq \sup_{\eta \in \mathcal{T}_{NT}} 2 \|f'_{it}(\zeta_0 - \zeta)\|_{P,2} (\|f'_{it}(\beta_0 - \beta)\|_{P,2} + \|f'_{it}(\pi_0 - \pi)\|_{P,2}) = O\left(\frac{s \log(p/\gamma)}{N \wedge T}\right). \end{aligned}$$

By taking $s = o\left(\frac{\sqrt{N}}{\log(p/\gamma)}\right)$, the rate condition for λ'_{NT} is satisfied, which completes the proof. □
